Redox Is short for reduction–oxidation reaction. It refers to a chemical reaction in which oxidation states of atoms are changed. The reaction involves the transfer of electrons between chemical species resulting in reduction process and a complementary oxidation process.

Introduction

Free radicals are normally formed during the intermediate steps of aerobic metabolism and a physiological level of free radicals is essential for successful fertilization by regulating sperm capacitation (Sharma and Agarwal, 1996). Free radicals are highly unstable due to the presence of unpaired electron(s). They attempt to gain electron(s) from other molecules in their vicinity and often result in a chain reaction. Reactive oxygen species (ROS) are a group of radical and non-radical derivatives of oxygen. The superoxide anion radical ($\cdot\text{O}_2^-$) is the most common ROS that is produced by spermatozoa. It is formed when an extra electron is added to molecular oxygen (O_2). The superoxide anion can be converted to other non-radical, such as, hydrogen peroxide (H_2O_2), which is relatively stable but still a powerful oxidant. Some free radicals containing nitrogen atoms such as nitrogen oxide (NO), peroxynitrite (NO_3^-), nitrous oxide (N_2O) and peroxynitrous acid (HNO_3) are called reactive nitrogen species. Reactive nitrogen species are often considered to be a subclass of ROS. ROS are very reactive in the presence of amino acids, lipids, and nucleic acids (Sharma and Agarwal, 1996).

The possible implication of ROS in male infertility have been reported since 1943 (MacLeod 1943). Since then, the detrimental effect of high ROS on sperm concentration, motility, morphology (Aziz et al., 2004), and DNA damage (Desai et al., 2009) have been described. Also, there are studies showing elevated ROS levels in 30%–80% of infertile men (Agarwal et al., 2006). The delicate balance in the cellular environment is maintained by the presence of scavenging system via enzymatic and nonenzymatic antioxidant pathways. Oxidative stress (OS) is the result of imbalance between production of ROS and the protective scavenging capacity of the antioxidants. It is more likely a result of a supraphysiological level of ROS rather than a low level of neutralizing antioxidants. Defective spermatozoa and leukocytes are the major sources of ROS in human semen (Kessopoulou et al., 1992).

Therefore, accurate assessment of seminal OS levels is a vital tool in the evaluation of infertile male. Laboratory evaluation of ROS is broadly divided into direct and indirect assays. Direct methods include cytochrome *c* reduction test, electron spin resonance, nitroblue tetrazolium technique, and chemiluminescence. Indirect methods measure the oxidized products by ROS. They include the Endtz test, measurement of lipid peroxidation products, measurement of sperm DNA fragmentation, and detection of post-translational modifications of proteins. In this chapter, the more widely used direct and indirect assays for measurement of ROS will be discussed in detail. Some tests, e.g. the Endtz test and sperm DNA fragmentation tests, will be discussed in other chapters. We will also present measurement of total antioxidant capacity (TAC) as another measure of OS status. Emerging techniques including measurement of oxidation–reduction potential (ORP) and proteomic analysis will be introduced.

Fig. 1 summarizes the different sources and deleterious effects of ROS. It also illustrates the different targets for ROS assays.

Fig. 1 Sources and adverse effects of ROS, and target of different OS assessment methods.

Direct Measurement of ROS

This ROS assay is the most widely utilized method for OS assessment. The amount of oxidation within the sperm cell membrane reflects the net oxidative imbalance between ROS production and the antioxidant concentration in semen (Agarwal et al., 2007). Direct measurements of ROS generally offer accurate results. However, their clinical application is often limited by the high cost (Agarwal et al., 2015). The more commonly used methods of nitroblue tetrazolium test (NBT) and chemiluminescence assay are discussed in more detail in the following sessions.

Nitroblue Tetrazolium Test

Nitroblue tetrazolium test or NBT test measures ROS generated by both spermatozoa and leukocytes. NBT becomes reduced by free oxygen radicals forming a blue-black compound, formazan. The reaction can be monitored spectrophotometrically or the stained cells can be scored histochemically. The NBT reaction reflects the ROS generating activity in the cytoplasm of cells. Moreover, results of NBT staining strongly correlate with ROS levels assessed by chemiluminescence (Esfandiari et al., 2003). Source of ROS, i.e. spermatozoa or leukocytes, can be distinguished by scoring the relative density of formazan granules. Different sources of ROS imply and point towards different pathological conditions. The test is readily available and inexpensive. The high sensitivity of the test potentially serves a good preliminary assessment tool for infertile men with suspected high ROS as the underlying etiology.

Chemiluminescence Assay

The chemiluminescence assay is a luminescence-based technique. Emitted light resulting from a chemical reaction between chemical reagents and oxidizing compounds is depicted and quantified by a luminometer (Fig. 2A). It is expressed as relative light units per second per 10^6 sperms ($\text{RLU s}^{-1} 10^{-6} \text{ sperms}$). A total of 11 tubes, including 3 blank, 3 negative control, 2 patient sample and 3 positive control, are labeled and analyzed (Fig. 2B). Different probes have been used in chemiluminescence assays. Each probe specifically measures a different type of free radicals in the sample, i.e. extracellular and/or intracellular. Luminol and lucigenin are among the most widely used probes. Luminol can measure the global level of ROS under physiological conditions. Both extra- and intracellular ROS including hydrogen peroxide and oxygen radicals are measured. On the other hand, lucigenin measures only extracellular ROS and it is specific for superoxide anions. Although the test measures both extra- and intracellular ROS with high sensitivity and specificity, it cannot measure multiple markers simultaneously and levels of ROS decline with time after ejaculation.

Fig. 2 Setup of direct ROS assay by chemiluminescence technique. (A) Luminometers for chemiluminescence and (B) preparation of tubes of ROS measurement.

Several studies have demonstrated that ROS levels measured by chemiluminescence may be able to distinguish good quality from poor quality samples. A sensitivity of 76.4%, specificity of 53.3%, positive predictive value of 82.1% and negative predictive value of 44.5% in differentiating infertile men from controls could be achieved with a cutoff value of $102.2 \text{ RLU s}^{-1} 10^{-6} \text{ sperm}$ (Agarwal et al., 2015).

Chemiluminescent assays can be used in patients with unexplained or idiopathic infertility. The results correlate with sample quality and also fertilizing potential of sperm in-vitro and in-vivo (Aitken et al., 1991). Patients who demonstrate high ROS levels in seminal ejaculate may benefit from antibiotic (in case of infection) or antioxidant treatments aiming at reducing ROS.

Indirect Assay of ROS

Unlike the direct methods, indirect assays measure the stable downstream end products of the peroxidative process or DNA damage. Indirect assays have the advantage of providing information of post-hoc ROS-related damage in addition to the value as a surrogate marker of OS level.

Measurement of Lipid Peroxidation

Polyunsaturated fatty acids are particularly susceptible to ROS. Breakdown of polyunsaturated fatty acids into lipid peroxides happens under OS. Aldehydic products including 4-hydroxynonenal (4-HNE), 8-isoprostane (IsoP) and malonaldehyde (MDA), are present as byproducts during the process of lipid peroxidation. They are relatively stable and act as a measure of the damage elicited to lipids by free radicals. Assessment of MDA by the thiobarbituric acid-reactive substance (TBARS) assay by colorimetry is the most commonly adopted method. The adduct formation between MDA and thiobarbituric acid is measured by color change depicted by microplate reader and converted using a standard curve. The test is relatively simple but non-specific.

Measurement of Post-Translational Modifications of Proteins

ROS can alter structure and functional integrity of specific proteins by reacting with amino acids. Several post-translational modification of proteins, including carbonylation and nitrosylation, commonly lead to dysfunctional proteins. Protein oxidation can be measured by colorimetric analysis with ELISA. The test is non-specific since most ROS will react with several amino acids to yield multiple products.

Measurement of Total Antioxidant Capacity (TAC)

It is feasible to measure levels of individual enzymatic or non-enzymatic antioxidants in a semen sample. However, TAC assesses the cumulative reducing ability of all antioxidants present in the semen and is the more commonly used technique. The reaction of seminal antioxidants against an oxidative reagent is measured by using a colorimeter or spectrophotometer, depending on the substrate (Agarwal et al., 2014; Roychoudhury et al., 2016). The colorimetric assay with the use of 2,20-azino-di-[3-ethylbenzthiazoline sulfonate] (ABTS) is most widely used among multiple TAC assays. The capacity of the seminal antioxidants in the sample to inhibit ABTS oxidation is compared to that of standard Trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid) and the result is expressed as micromoles of Trolox equivalent and the test is also known as Trolox equivalent antioxidant activity (TEAC) assay.

The lack of predictive value limits the application of TAC alone to routine infertility assessment. Its limitation is addressed by a recent study which established a cutoff for TAC assay. A diagnostic cutoff value of 1947 μM Trolox in seminal plasma distinguishes the prevalence of OS in infertile patients compared with healthy men with a sensitivity of 59.5% and specificity of 63.0% (Roychoudhury et al., 2016). The method of colorimetric TAC assay has been standardized and a kit has been used successfully with seminal plasma (Mahfouz et al., 2009).

ROS-TAC Score

The score is a novel measure of OS and minimizes the variability of ROS and TAC assays alone. Standardized values are generated from ROS and TAC results from healthy controls and a scale is created using principal component analysis and controls as reference points. The measure is superior to ROS or TAC alone in differentiating fertile from infertile men. Infertile patients have significantly lower ROS-TAC score. It is also reported that a lower score in infertile men is correlated with higher risk of prolonged inability to conceive (Sharma et al., 1999).

Proteomic Analysis

Proteomics is a large scale study of proteins by using bioinformatics tools. The use of proteomics in studying human biological system is gaining popularity in recent years and opens a new research area. Proteomic analysis in spermatozoa and seminal plasma measures ROS-induced protein alterations and demonstrates the change in sperm function as a result of post-translational modification of proteins. Global change in proteomic profiling of human spermatozoa and seminal plasma under OS conditions has been studied. It is shown that infertile patients have differential expression of proteins in relation to variations in ROS level (Ayaz et al., 2015). The identification of differentially expressed proteins in infertile men represent potential markers for ROS-induced male infertility. The understanding of function of differentially expressed proteins may reveal the underlying etiological relationship between OS and male infertility.

Redox Potential/ORP

Measurement of ORP represents an indirect assay of OS status by measuring the redox balance in a given biological system. The result reflects the overall oxidant and antioxidant activity in a sample. It differs from other assays that, rather than measuring a few markers, all known and unknown oxidants and antioxidants are measured in real time with a single test. Changes in redox potential in various body fluid has been correlated with severity of illness and mortality (Rael, 2009).

The introduction of the MiOXSYS System (Aytu BioScience, Inc.) presents a novel and comprehensive way to measure seminal OS (Fig. 3). ORP provides a snapshot of redox potential by applying a low voltage current to the sample. The results are expressed as ORP 10^{-6} sperm mL^{-1} after normalizing the sperm concentration. By using the MiOXSYS System, only a small volume of 30 μL of liquefied neat semen is required and the whole process takes less than 4 min. Sensitivity and specificity of 70.4% and 88.1% has been reported with ORP cutoff at 1.57 mV 10^{-6} sperm (Agarwal et al., 2017). Furthermore, the ORP measurement is not affected by the age of the specimen for up to 2 h. Also, fresh or frozen semen samples or seminal plasma can be used with consistent results. The positive association of ORP with conventional semen parameters has been clearly demonstrated (Zorn et al., 2003).

The clinical uses of ORP are many fold as a ready-to-use ORP assay kit potentially provides a fast screening tool in office. The result may be valuable in guiding further investigation and management plan. The measurement of ORP in cryopreserved semen samples may predict success of assisted reproductive technology. The test is also helpful in selecting patients to treatment of OS, as well as monitoring treatment response. The measurement of ORP addresses the drawback of other OS assays by providing a multi-faceted full picture of OS status. It may prove itself an easily applicable and comprehensive measure of OS in the assessment of infertile male. Table 1 compares the various more commonly used techniques in measuring seminal OS.

Types of Samples for ROS Measurement

ROS measurement can be applied to various types of semen samples. On the other hand, it is important to know the type of semen sample used in order to interpret the test result correctly.

Neat (or Unprocessed) Seminal Ejaculate

Seminal ejaculate comprises of both spermatozoa and secretions from various male sex glands. It also contains round cells and epithelial cells, and in pathological conditions, leukocytes. The setting is ideal in indicating the de novo levels of OS in the whole ejaculate.

'Wash and Resuspend' Sample

The seminal plasma which confers protection to spermatozoa is removed from a liquefied semen specimen by centrifugation. Sperm pellet is then washed and resuspended in sperm wash medium. Only cellular components including spermatozoa, round cells, white blood cells and debris are analyzed.

Fig. 3 MiOXSYS analyzer and sensor for measurement of oxidation–reduction potential: (A) analyzer and (B) sensor.

Table 1 Advantages and disadvantages of common techniques in oxidative stress measurement

Assay	Advantages	Disadvantages
Nitroblue tetrazolium test (NBT)	- Measures ROS generated by both spermatozoa and leukocytes - Source(s) of ROS can be differentiated, i.e. spermatozoa and/or leukocytes - High sensitivity - Inexpensive	- Scoring of relative density of formazan granules inside spermatozoa and leukocytes histochemically requires expertise - Possible inter-observer variability - Not a quantitative measure of ROS
Reactive oxygen species (ROS) by chemiluminescence	- Global level of ROS under physiological conditions can be assessed by luminol probe - Different systems of probe can be applied to the system - High sensitivity and specificity - Reference value has been reported	- Test results are affected by variables including semen age, semen volume, repeated centrifugation and background luminescence - Time-consuming - Requires expensive equipment
MDA (malonaldehyde)	- Measures byproduct of lipid peroxidation which is relatively stable compared to ROS - The measurement of MDA-TBARS (thiobarbituric acid reactive substances) adduct by colorimetry is relatively simple	The result is non-specific and provides post hoc measure only
TAC (total antioxidant capacity)	- Measures cumulative reducing ability of all antioxidants in seminal plasma - Rapid colorimetric method is available	- Measures non-enzymatic antioxidants only - Requires expensive microplate reader - The predictive value has yet to be established
ROS - TAC score	Better predictor compared to ROS and TAC alone by minimizing variability	- Requires statistical modeling - Provides a prediction of oxidative stress in a sample, but not a direct measure of ROS nor TAC
ORP (oxidation–reduction potential)	- Measures all known and unknown oxidants and antioxidants - Provides real-time assessment of redox balance - Quick and relatively simple test with ready-to-use sensor and analyzer - Applicable to various types of samples including seminal ejaculate or seminal plasma, both fresh and frozen - Requires small volume of semen for analysis - Test result not affected by semen age for up to 2 h	- Affected by viscosity of the sample - Does not provide information on individual oxidant and antioxidant which lead to the imbalanced redox state

Sample after Sperm Preparation Techniques

Swim up method select spermatozoa with high motility for ROS detection. The seminal plasma is removed from sample by centrifugation before swim up. Supernatant obtained after swim up is centrifuged again and sperm pellet resuspended for ROS measurement.

The use of double density gradient separates immature and mature spermatozoa in a sample by centrifugation. Immature sperm with poor motility and abnormal morphology, and mature sperm with good motility and normal morphology can be individually studied for ROS levels.

Conclusion

Oxidative stress is a result of imbalance between ROS levels and the scavenging antioxidant capacity. Elevated ROS levels are present in 30%–80% of infertile men. Its implication in the etiology of male infertility and sperm dysfunction resulting in lipid peroxidation of the cell membrane, sperm DNA damage and apoptosis in spermatozoa has been reported. Elevated ROS represents a common mediator between various disease conditions and decreased reproductive potential. Therefore, development of a simple and reliable technique of ROS measurement is important in the evaluation of infertile men. Direct ROS assays, including nitroblue tetrazolium test and chemiluminescence test, are the most widely used methodology for ROS measurement. The NBT assay is able to differentiate the source of ROS, i.e. spermatozoa and/or leukocytes. Chemiluminescence tests are robust and measure different intra- and extracellular ROS by using different probes. These tests are highly sensitive and specific. However, the result is affected by multiple factors including semen age. Chemiluminescence is also limited by the use of expensive equipment and technical expertise. On the other hand, indirect ROS assays measure the stable downstream products as a result of ROS-induced damage. Measurement of lipid peroxidation and post-translational protein modification are some of the techniques. The assessment of total antioxidant capacity provides a multifaceted assessment of OS and may confer more comprehensive information in combination with ROS measurement in the form of ROS–TAC score. Novel approaches including measurement of proteomics and oxidation–reduction potential opens new possibilities for evaluation of OS. They also offer an opportunity in understanding the nature and deleterious effect of ROS on male reproductive function.

Sperm Morphology

Susan A Rothmann and Anna-Marie Bort, Fertility Solutions, Cleveland, OH, United States

Role of Sperm Morphology

Semen analysis is a “gateway” laboratory test for male fertility evaluation, providing an initial screening test for assessing male reproductive health. Its components of spermatozoa (sperm) count, motility and morphology indirectly measure testicular health, spermatogenesis, spermiation and some sperm functional properties and can direct diagnostic or therapeutic paths for fertility treatment. Sperm morphology involves classification of sperm into a variety of types based on shape and structures that can be seen in stained semen smears using high magnification (1000×) brightfield microscopy.

Historically, sperm morphology is a predictive measure of fertility potential and treatment outcome. It is associated with fertility and pregnancy rates for natural and assisted fertilization (Aziz et al., 1996; Burr et al., 1996; De Vos et al., 2003; Francavilla et al., 1990; Elizur et al., 2004; Guzik et al., 2001; Hauser et al., 2001; Kruger et al., 1986, 1988; Lindheim et al., 1996; Menkveld et al., 1996; MacLeod, 1962; MacLeod and Gold, 1951; Toner et al., 1995), including fertilization and implantation outcomes in assisted fertilization (Aziz et al., 1996; Bourne et al., 1995; De Vos et al., 2003; Kruger et al., 1988; Osawa et al., 1999; Porcu et al., 2003; Salumets et al., 2002). It is also associated with in vitro measures of sperm binding to the oocyte zona pellucida and hyaluronic acid (Bastiaan et al., 2003; Liu and Baker, 1992, 2003; Liu et al., 2003; Menkveld and Kruger, 1996; Menkveld et al., 2003; Prinosilova et al., 2009; von Bernhardt et al., 1990). These relationships made sperm morphology a tool for choosing therapies such as varicocelectomy (Schatt et al., 1998), intra-cytoplasmic sperm injection (ICSI) or in vitro fertilization (IVF) (Porcu et al., 2003; Liu et al., 2003).

Sperm morphology also is a useful indicator of exposure to environmental and occupational toxicants such as perchlorethylene, lead, mercury, perfluorochemicals and many chlorinated or brominated hydrocarbons (Buck Louis et al., 2014; Katz, 1991; Moorman et al., 2000; Royster et al., 2000; Schrader et al., 1987, 1992). Morphology remains unchanged during overnight shipping making it a useful parameter in clinical studies requiring remote sample collection (Royster et al., 2000).

Basic Human Sperm Anatomy

The mature spermatozoan has three main regions (Fig. 1). The head of a human sperm is essentially all nucleus, tightly compacted into a very small elliptical shape approximately 4–5.5 µm long and 3 µm wide. For comparison, a red blood cell is 7–8 µm in diameter, nearly twice as large as the sperm head. The sperm head is covered partially by the acrosome, a cap-shaped organelle that contains enzymes and receptors for oocyte binding and fertilization (Fig. 2). The midpiece is 1–1.5 times the length of the head and contains dense outer longitudinal fibers that encircle a central axoneme, surrounded by a spiral array of mitochondria that provides ATP for flagellar movement (Figs. 2 and 3). The principal piece or tail is a 45–50 µm long flagellum used for propulsion through the female reproductive tract and penetration of the oocyte. Cytoplasmic remnants that represent errors in spermiation can often be seen attached to any part of the sperm but are most commonly seen on the midpiece. Immature sperm precursors can be observed in semen as spermatids or spermatocytes when differentiation is disrupted.

Sperm Classification Schemes

Many sperm classification schemes have been described during the last 60–70 years, but two main types are used now in clinical practice, Tygerberg Strict or Traditional Non-Strict. Validation of classification schemes typically compared the percentage of normal sperm to pregnancy or fertility treatment outcome, showing that normal sperm were ubiquitous in men of proven fertility and

Fig. 1 Basic anatomy of a human spermatozoan.

Fig. 2 Cross section of sperm in coronal and sagittal views.

Fig. 3 Diagram of the human sperm midpiece.

relatively infrequent in infertile men (Kruger et al., 1988; MacLeod and Gold, 1951; Menkveld et al., 1990, 1991; Rehan et al., 1974). Table 1 summarizes the main differences between these types of classifications.

The first of the Traditional schemes was published by MacLeod (1962) with subsequent similar variations (Adelman and Cahill, 1989; David et al., 1975; Eliasson, 1971; Freund, 1966; World Health Organization (WHO), 1980, 1987, 1992). Normal was defined as an idealized sperm cell with an oval head, straight and regular midpiece with a tail approximately 10 times the length of the head (Fig. 4). Borderline normal sperm were classified as normal. These schemes have lower reference limits of 30%–50% normal and medians of 60%–80%.

In the mid-1980s, Roelof Menkveld in Tygerberg South Africa took a different approach to classification (Menkveld et al., 1990, 1991). Assuming that the morphologically-uniform post-coital sperm present in upper endocervical mucus represented a functional subset of ejaculated sperm, he used this homogeneous population of mostly oval-headed sperm as a reference normal prototype, defined very critically. He also defined two specific variants as borderline normal. Unlike previous schemes, the Tygerberg Strict

Table 1 Sperm classification schemes

	<i>Traditional criteria</i>	<i>Strict criteria</i>
Names	MacLoed, Eliason, David WHO 1st–3rd	Tygerberg, Menkveld, Kruger WHO 4th and 5th
Borderline normal classification	Normal	Abnormal
Lower reference limit	30%–50%	4%
Median	60%–80%	14%

Fig. 4 Photomicrograph of prototypic normal human sperm stained with modified Papanicolaou Stain.

Criteria classified borderline as abnormal. The scheme consequently has a lower reference limit of 4% normal and a median of 14% (Cooper et al., 2010). The Tygerberg Strict Criteria became the recommended classification scheme in the Fourth and Fifth Editions of the WHO semen analysis manuals (World Health Organization, 1999, 2010).

Problems in Test Performance Have Led to Loss of Predictive Value

In spite of its known value, sperm classification is difficult to learn and perform in a consistent manner. Proficiency testing results demonstrate a wide variety of expertise where the variation among participating labs often encompasses most of the clinical range from 0% to 100% normal forms (Keel et al., 2000; Kinzer et al., 1998; Morbeck et al., 2008). Why is sperm morphology so difficult to perform in a standard way? Unlike many other species, human sperm are extremely pleiomorphic in several respects: many subtle variations of normal exist and many irregular and abnormal forms are present (Freund, 1966; Katz et al., 1986). Identification of different morphologic forms is difficult when they display continuous variation rather than precise and unique typologies (Bedford et al., 1973; Freund, 1966; Katz et al., 1986; Souchier et al., 1978), as exemplified in Fig. 5. A discrete form (e.g., oval or round) along the morphologic spectrum may be readily identifiable, but intermediate variations can be difficult to recognize and categorize (Fig. 6).

Fig. 5 Geometric progression of forms from round to elliptical to pyriform illustrates the difficulty of identifying discrete differences at individual points along the spectrum.

Fig. 6 Diagrammatic representation of the dilemma of categorizing a shape that is not clearly abnormal or normal.

Although Menkveld did not intend to define only visually “perfect” sperm as normal, as the system was adopted over time, many analysts became much more conservative in their classification, assigning normal only to “perfect” sperm. As a consequence, the degree of “strictness” varies from lab to lab, as shown in proficiency test results (Keel et al., 2002). When there is subjective application of classification schemes, individual observers or laboratories often develop variations, making comparison of results from different labs impossible (Baker et al., 1994; Chong et al., 1983; Davis and Gravance, 1994; Davis et al., 1995; Freund, 1966; Keel, 2004).

The authors’ own NIH funded research highlights the difficulty obtaining classification consensus (Bort et al., 2014; Rothmann and Bort, 2015). In a survey of 99 international experts, good agreement was present when the sperm had an obvious abnormality (Fig. 7). However, when the sperm was not grossly abnormal, agreement was terrible, with equal numbers of analysts classifying a cell in the three possible categories of normal, borderline or abnormal. Most experts reported classification using Strict Criteria but clearly there was no standard application in use.

As if classification variation was not a big enough problem, the names of various physicians and organizations (e.g. Kruger, WHO 4th and 5th Edition Manuals) who endorsed Menkveld’s Tygerberg Strict Criteria began to be used as the scheme name, creating an impression that multiple Strict schemes exist. However, they are all the same scheme using the same references to Menkveld’s original work. The name confusion is evident in proficiency testing programs that erroneously stratify answers by these many names, and often these different categories have different results and ranges of answers, which makes no sense.

Compounding the problem, Menkveld’s discrete definitions of two types of sperm with specific characteristics that should be classified as borderline normal sperm were lost on most laboratory analysts, who now typically classify anything not “perfect”

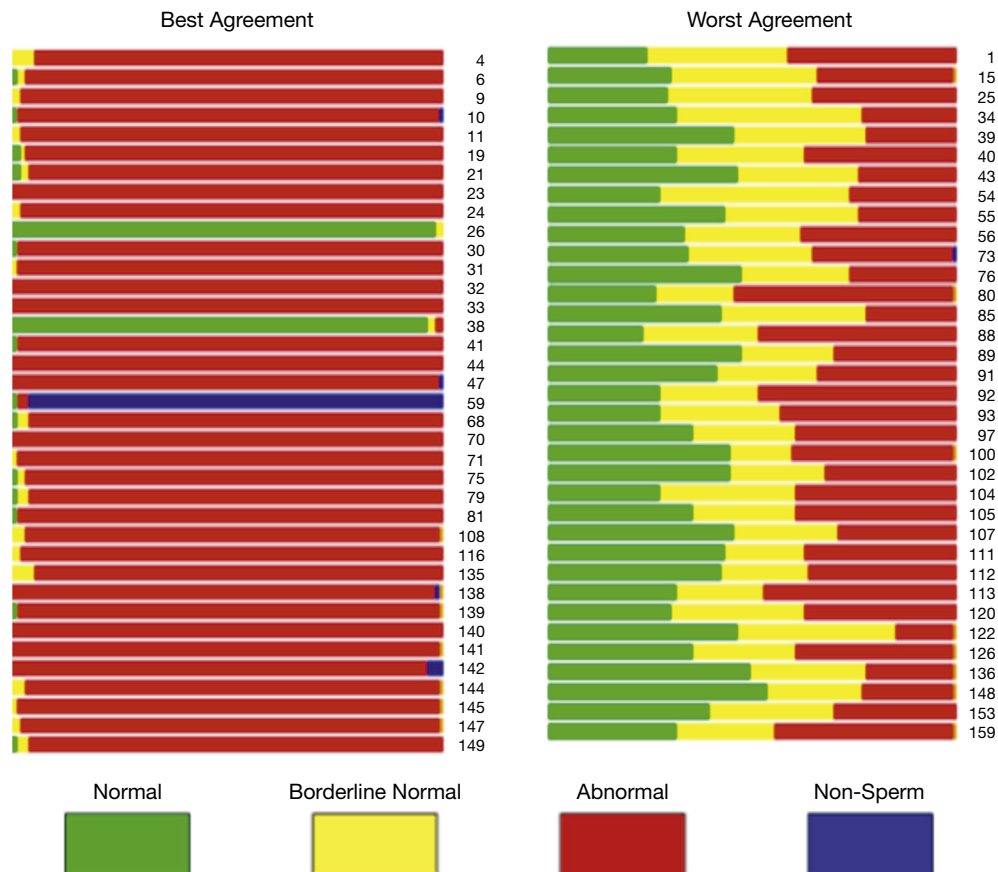

Fig. 7 Expert agreement on sperm classification. Each bar includes classification of a sperm photograph by 99 international analysts. The size of each color within the bar represents the cumulative number of analysts classifying in a specific way as shown by the color. Numbers to the right of each bar indicate photograph number.

(by their definition) and not clearly abnormal into the borderline normal category. Since these forms are combined into the abnormal category in Strict classification, the result is downward classification drift to the point where in many labs, few normal sperm are identified even in the semen of known fertile men (Menkveld, 2010).

The world-wide drop in ability to discern normal from abnormal forms led to the loss of predictive value for sperm morphology in many labs. At Mayo Clinic, a strong relationship between percent normal sperm and intra-uterine insemination outcome was completely lost as their lab analysts became more and more conservative in their classification (Morbeck et al., 2011). The problem is universal enough that some authors suggest that sperm morphology has no relevance in semen analysis (Gatimel et al., 2017). To the contrary, the problem is a profound loss of good laboratory practice throughout andrology laboratories.

The Solution—A Rational Method of Classification

Dr. Matthew Freund wrote 50 years ago “human sperm morphology has suffered from being subjective, qualitative, non-repeatable, and difficult to teach to students and technicians” (Freund, 1966). Numerous attempts to standardize sperm classification have met with limited successes and more often outright failures. All of these stem from the same problem, the lack of a consistent method or process for systematically evaluating descriptive characteristics. So how is this accomplished in other fields? Taxonomists and pathologists typically use algorithms to standardize classifications of organisms and cell types (Winston, 1999). Most sperm analysts use non-systematic practices of classification, based on different hierarchies of analysis and often different sperm morphology descriptors. Often analysts decide a sperm is normal or abnormal based on cursory examination. To develop a standard method, the authors’ research led to a novel heuristic sperm classification algorithm that could be used with existing definitions for the Tygerberg Strict Criteria Scheme or any of the Traditional Schemes.

The algorithm is a 12 query dichotomous key, that is, it uses twelve sequential binary questions that ask whether a specific characteristic is present (Fig. 8). If yes, classification is determined. If no, the analysis proceeds to the next query. If none of the abnormal or borderline normal traits are present, the sperm is classified as normal (Rothmann et al., 2013; Bort et al., 2014; Rothmann and Bort, 2015). The queries impose a standard method of classification that reduces subjective speculation about whether a sperm is normal or abnormal.

Morphology results using the Algorithm closely match the 2010 WHO reference distributions with a median of 14%. It produces reproducible results between technologists, permits simultaneous Strict and Traditional classification and reduces the tendency for overly conservative analysis that has diminished sperm morphology’s predictive value. Results obtained using the Algorithm showed predictive value associated with fecundity in the NIH Life Study (Buck Louis et al., 2014). Using prospectively measured time to pregnancy, Strict and Traditional morphology were associated with significantly shorter time to pregnancy fecundability odds ratios (FOR) > 1. Significantly longer time to pregnancy with FORs < 1 were observed for amorphous and round sperm heads and neck/midpiece abnormalities. Workshops at the American Society of Andrology demonstrated that the method is easy to learn and improves consensus (Bort et al., 2014).

Specific Sperm Abnormalities

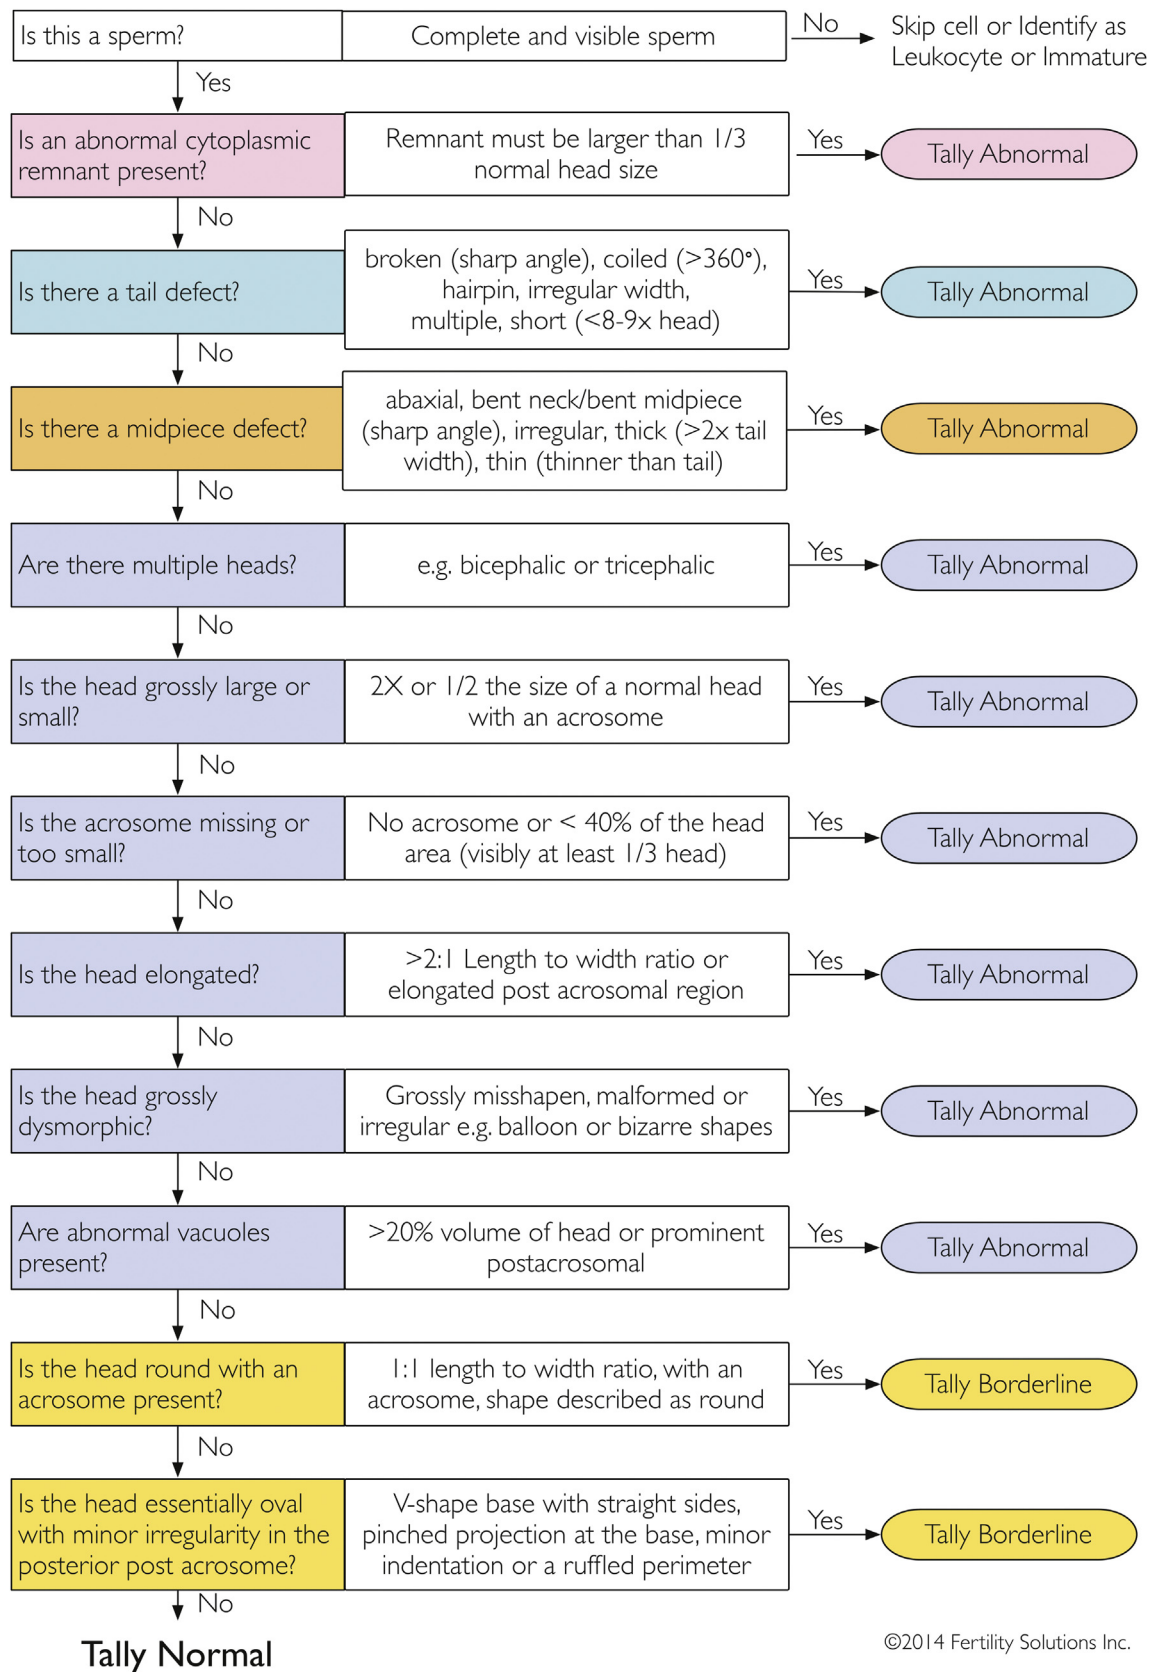

Although the most recent edition of the WHO Manual did not advocate differential analysis of the sperm, many authors disagree (Amann, 2010; Auger et al., 2016; Eliasson, 2003; Menkveld, 2010). Some sperm morphology variants are absolutely linked to pathology and increasingly are linked to specific human genes (Carrell, 2007; Krausz and Sassone-Corsi, 2005; Golas et al., 2008). As more are identified, the value of performing a sperm morphology differential should be increased because it will serve as a screen for investigating high probability genes. Specific sperm anatomic defects are summarized below. Many sperm have more than one abnormality. Various types of multi-entry differentials can be used to classify all defects or the predominant one in each of the three regions of each sperm (head, midpiece and tail) plus any abnormal cytoplasmic remnant.

Cytoplasmic Remnant

Cytoplasmic remnants, also termed cytoplasmic droplets and excess residual cytoplasm, should normally be removed from the round spermatid during passage through the epididymis. Cytoplasmic remnants smaller than one-third the head area of a normal sized sperm are considered normal, but remnants larger than one-third that size are abnormal. Excess cytoplasm reduces sperm function due to release of reactive oxygen species (Cooper, 2011). Remnants are usually located in the neck/midpiece region, but occasionally appear along the tail or around the head.

Tail

Many abnormalities of the sperm flagellum are found, including bent or broken, hairpin, short, coiled and thick. When seen in large numbers, they may be associated with athenozoospermia (poor motility). Several genes have been implicated in defective tail morphology. Multi-flagellate sperm have been linked to a variety of chromosomal aberrations (Sun et al., 2006).

Fig. 8 Sperm confirm algorithm for morphology classification.

Midpiece

Thick midpieces are 1.5–2 times wider than normal and typically resemble a tapered golf tee shape. Ultrastructurally, they show mitochondrial misalignment and are associated with low sperm aster formation rates, probably due to dysfunction of the centrosome contained within the midpiece (Ugajin et al., 2010). Thin midpieces occur when the mitochondrial sheath loosens and separates from the underlying axoneme, exposing the thinner filamentous core (Ben Khelifa et al., 2014; Chemes et al., 1998). These disorders have been linked to a variety of gene mutations. Midpieces that are bent or have abaxial orientation to the tail have disordered or missing annulus (Lhuillier et al., 2009).

Multiple Heads

Bicephalic and tricephalic sperm arise from non-disjunctive events and failure of cytokinesis. Depending on the stage affected, the entire sperm including midpiece and tail also may be replicated.

Elongated Heads

Elongated heads where the length is two times the width or greater result from sperm maturation arrest during spermiation. Elongation can be manifested as an overall elongated shape like a cigar, pyriform where the post-acrosome is elongated to a point, or long dumbbell shape. Elongated sperm are more common in men who have experienced extensive febrile illness or hyperthermia associated with prolonged hot bath exposures (Eliasson, 1971; MacLeod and Gold, 1951; Mieusset et al., 1987).

Head Size

Head size abnormalities are associated with lower fecundity. Sperm with macrocephalic heads have a high frequency of polyploidy that arises from early non-disjunctive events (Sun et al., 2006). The rare syndrome of 100% macrocephaly is associated with mutations in the aurora kinase (AURKC) gene (El Kerch et al., 2011). A reversible form of macrocephaly is associated with sulphasalazine (Cosentino et al., 1984). Sperm with small sperm heads usually have small acrosomes leading to lower fertilization potential (Menkveld et al., 2003). Sperm size defects are found in higher numbers in men with testicular germ cell tumors (Auger et al., 2016).

Acrosome Absence or Size

When the acrosome is absent, the sperm usually has a spherical shape, appearing round on the stained smear. When most or all of the sperm are round without acrosomes, a rare clinical condition called globozoospermia is present. These sperm cannot penetrate the ovum but can be fertile if injected into the ovum using ICSI. Several gene mutations have been identified in globozoospermia, especially deletions of DPY19L2 on chromosome 12 that plays a role in acrosome formation and sperm elongation (Coutton et al., 2015; Elinati et al., 2012; Kosciński et al., 2011; Zhu et al., 2013).

In critical settings, measurement may be required. Small acrosomes that are less than one third of the head area are associated with premature sperm cell death (Menkveld et al., 2003) and early embryo development failure (Kihaila et al., 2003). Large acrosomes appear to have the same functional ability as normal size acrosomes (Menkveld et al., 2003).

Dysmorphic Heads

The presence of bizarre shaped heads with severe deformities and irregularities is common in human ejaculates but rarely observed in cervical mucus.

Vacuoles

Vacuoles are voids and craters in the surface of the sperm. The presence of a few small vacuoles is not abnormal, but multiple vacuoles that occupy > 20% of the head area and prominent vacuoles in the post acrosome are associated with reduced fertilizing capacity. Unfortunately, vacuoles can be induced by air drying, leading to significant over-classification of the abnormality in semen smears that are not fixed immediately while the semen is still wet. If vacuoles are found in all sperm and every ejaculate, procedures for smearing and fixation should be modified.

Borderline Normal Heads

Menkveld defined specific head shapes for this category with slight deviation from oval that include round heads with an acrosome or heads with minor irregularity in the post-acrosome ("V" shape without elongation, pinched projection at base of head, or irregular perimeter (Menkveld et al., 1990). All are observed in sperm that exhibit binding to hyaluronan in vitro (Prinosilova et al., 2009), suggesting that they have normal function.

Laboratory Practice

No matter what the classification scheme or method to employ it, good laboratory practice is the underpinning of quality sperm morphology. Unfortunately, it is often lacking in semen analysis (Chong et al., 1983). Automation has been largely unsuccessful, in part because sperm are so small compared to the other cells typically analyzed in the clinical laboratory, and because the market for such instrumentation is small. Manual microscopy remains the most reliable method.

Before the cells can be examined, the semen must be smeared correctly and fixed while wet to reduce artifacts of air drying like vacuolization and to improve semen adherence to the slide. Alcohol-based spray fixatives should be applied immediately after the smear is made. The gold standard for staining sperm morphology smears is modified Papanicolaou stain, which does not stain the background protein and mucoid material in the seminal plasma, giving excellent contrast to the sperm features and making sperm fine structures easier to discriminate. Many common stains commonly used for semen analysis are appropriate for blood but not semen, such as Wright Giemsa or commercial quick stains. These stain the background seminal plasma, dramatically lowering contrast and often obscuring features and structures, including tails.

Usefulness of morphology also depends on good training and a rigorous quality control (QC) program to establish and monitor consistency and agreement among technologists, as required by regulatory and accreditation agencies (Franken et al., 2000). One smear analyzed repeatedly over long periods of time shows classification stability and gives trending data that can be lost if too many QC smears are rotated (Rothmann et al., 2013; Rothmann and Bort, 2015). If the lab reference range differs from the WHO reference interval and median, the QC smear results should be established by a lab with techniques that produce with WHO 5th distribution of values. Virtual smears and high quality photographs of individual sperm cells allow exact comparison among multiple analysts and can help prevent drift and shift in classification.

Reference Limits

Reference intervals give an expected range of values of a given parameter within a defined population group. The median, upper and lower limits can be calculated from the group's results. For sperm morphology, the upper limit is not known to have negative consequences and is disregarded. The lower limit defines the value that is considered abnormal and is usually the lower 5th or 10th centile, depending on the rigor of testing and confidence in the population.

In 2010, reference intervals for sperm morphology using the Tygerberg Strict Criteria were published, based on retrospective review of publications that were considered comparable (Cooper et al., 2010). Sperm morphology of "Fertile Fathers," men whose partners became pregnant within 12 months of unprotected intercourse, had a lower (5th centile) reference limit of 4% normal forms and a median of 15% normal. The study also defined limits for a "General Population" group of men whose fertility was not known (Table 2).

A laboratory's range of values should encompass the spectrum described by the reference population. For Strict classification, 95% of results should be higher than 4%–5% normal with a median of 14%–15% normal. Too many analysts and physicians misinterpret lower reference limit as the median. Although men who are undergoing fertility evaluation with their partner will have a downward shift in the distribution of percent normal sperm, it is highly unlikely that all of them will be below the lower reference limit, especially if fertilization and pregnancies are occurring. Labs whose normal morphology never exceed 5%–10% normal should recalibrate their classification.

Summary

Sperm morphology is an important component of male reproductive health evaluation with predictive value when carefully performed. The consequences of incorrect sperm classification can be expensive, invasive treatment or inappropriate focus on finding pathology in the female partner. The need for improvement in morphology performance is essential. With intra-cytoplasmic sperm injection the most common treatment of male infertility, abnormal genes that cause sperm morphology defects could be transmitted to offspring. Rational classification methods based on standardized algorithms, high quality microscopic techniques and good quality control could restore and improve the predictive value of sperm morphology classification and its utility as a screening tool for male reproductive health.

Table 2 Normal sperm morphology reference limits for strict criteria

Reference group	# Men in reference group	Lower reference limit	Median	Total normal in ejaculate (million per mL)
Fertile fathers with time to pregnancy 12 months or less	1851	4%	15%	37
Men unscreened for fertility (general population)	137	5%	14%	29

Laboratory Evaluation of Sperm in Cervical Mucus

Grace M Centola, Reproductive Laboratory and Tissue Bank Consultant, New York, NY, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Determination of the capacity of the sperm to pass through the woman's cervical mucus at the time of intercourse is an important adjunct for clinicians to use in diagnosis and management of the infertile couple. The choice of which additional test(s) to perform, and when to perform them, are dependent on the initial evaluation of the male and female partners.

With natural conception, the sperm are deposited at the cervix, must swim through the cervical mucus into the uterus, and pass into the oviducts or fallopian tubes to arrive at the site of fertilization. Since the cervical mucus is the first barrier for the sperm entering the female reproductive tract, assessment of the interaction between the sperm and the cervical mucus can be an important step in fertility diagnostics.

An in vivo test of sperm–cervical mucus interaction is referred to as the postcoital test (PCT), Sims test, Sims–Huehner test, or Huehner test. In vitro laboratory assessment of sperm–cervical mucus interaction is referred to simply as a simple slide test or Kremer Test, and the capillary tube test or Kurzrock–Miller test (Mortimer, 1994; WHO, 2010).

Cervical mucus is conducive to sperm penetration only for a short time at the middle part of the female's ovulation cycle, from approximately day 9 of a normal 28-day cycle to the day of ovulation (WHO, 2010). At most times during a woman's cycle, the cervical mucus is thick and does not allow easy penetration by motile sperm. However, at midcycle, under the influence of hormones such as estrogen, the cervical mucus changes, becoming thinner and more abundant allowing easy passage of the motile sperm (WHO, 2010). It is at the midcycle time when both the quality of the cervical mucus and the activity of the sperm can be assessed. "Spinnbarkeit" is a term used to describe the elasticity or stretchability of the mucus, and "ferning" is the visual appearance of midcycle cervical mucus that is dried on a glass slide. Both Spinnbarkeit and ferning show characteristic patterns in midcycle cervical mucus as compared to other times during a woman's cycle. Abnormal amount and quality of midcycle cervical mucus is a cause for concern. Abnormal numbers and/or motility of sperm in normal midcycle cervical mucus are also a cause for concern. Both may be indications to attempt to improve the mucus with medications, or bypass the hostile cervical mucus to deposit motile sperm directly into the uterus (intrauterine insemination; IUI) or other forms of assisted reproduction which are very common treatment options.

Postcoital Test

A PCT is performed by the gynecologist or reproductive endocrinologist to determine if the midcycle cervical mucus is conducive to sperm penetration. Instructions are provided for ovulation timing with the assumption that at, or right before midcycle, the cervical mucus is receptive to sperm penetration and survival. The couple is instructed to have intercourse, and the female partner to appear at the physician's office 3–4 h after intercourse. Alternately, the couple is instructed to have intercourse the night before the scheduled test, and the cervical mucus is checked at the physician's office the next morning (WHO, 2010).

A smear of the cervical mucus is taken by the physician and examined under a microscope. There should be an adequate amount or volume of the cervical mucus, and the consistency should be watery minimally viscous midcycle mucus (Moghissi, 1976; WHO, 2010). The cervical mucus should show adequate stretching, Spinnbarkeit, and is scored as 0 (low stretchability) to 3 (9 cm or more stretching). Ferning is scored after a sample of mucus is air dried on a glass slide. Once mucus has dried on the slide, crystallization presents as a fern-like appearance, with branching of the "ferns." Ferning is scored on a scale of 0 (no fern formation) to 3 (significant fern stems) (Moghissi, 1976; WHO, 2010). The cervical mucus is rated as good mucus which favors sperm penetration, or unfavorable (Moghissi, 1976; Bush et al., 1997; WHO, 2010).

The mucus smear is also examined for the presence of sperm. It is desirable to see 10 or more sperm per high power field examined. Additionally, the motility of the sperm in the mucus is rated as progressive, motile but nonprogressive, or immotile. The PCT is negative if no sperm are found in the mucus. Rapidly motile sperm seen in the cervical mucus some 9–14 h after intercourse indicates that the cervical mucus is good quality and not hostile to sperm. It is then assumed that sperm would sufficiently progress through the cervix and into the uterus and fallopian tubes (Moghissi, 1976; Bush et al., 1997; WHO, 2010). Considering the results, the physician will interpret a negative PCT to result from incorrect midcycle timing, possible lack of intravaginal ejaculation, ejaculatory dysfunction, and abnormal semen analysis (if an analysis had not been previously performed). A negative PCT should be repeated to confirm these findings.

Laboratory Tests for Sperm–Cervical Mucus Interaction

Laboratory or in vitro tests of sperm–cervical mucus interaction are performed following a negative PCT, and to determine if the "problem" is with the sperm or the cervical mucus. Such tests compare the female partner's cervical mucus with donor cervical mucus, and the male partner's sperm with donor sperm in cross-over testing. Commercial laboratory test kits are also available

for use in sperm–cervical mucus interaction testing (Sharara et al., 1994; Niederberger et al., 2006). The concentration of sperm that penetrates into the cervical mucus, rather than how far the sperm has traveled in the mucus, has been suggested as a laboratory-based sperm function test (Aitken, 1993; Ola et al., 2003).

In vitro slide tests include a simplified slide test called the Kurzrock–Miller test and a capillary tube test or Kremer test (Kremer, 1965; Mortimer, 1994; WHO, 2010). The male partner's sperm is tested with both the female partner's and donated midcycle cervical mucus. Good quality donor sperm is also tested with samples of midcycle mucus. Bovine cervical mucus or synthetic gels have been substituted for human cervical mucus in these slide tests (WHO, 2010; Ivic et al., 2002). In vitro slide tests include a simplified slide test called the Kurzrock–Miller test and a capillary tube test or Kremer test (Kremer, 1965; WHO, 2010) (Mortimer, 1994).

The Kurzrock–Miller test is a simple slide test in which a drop of semen is placed against a drop of midcycle cervical mucus under a coverslip (Mortimer, 1994; WHO, 2010). Within a few minutes, the seminal fluid pushes into the cervical mucus, and a lead sperm can be seen swimming into the mucus. After 30 min, the slide is examined under a microscope to determine if, and how far, the motile sperm penetrated into the cervical mucus. A normal result is seen when multiple progressively motile sperm are found in the mucus. An abnormal result is seen when little or no sperm progress into the cervical mucus, or, if the sperm do penetrate the mucus interface, the sperm are immotile or “shaking” in place with no forward progression (Mortimer, 1994; WHO, 2010).

The capillary tube test or Kremer test measures the ability of sperm to penetrate into a column of donor and patient cervical mucus (Kremer, 1965; Mortimer, 1994; WHO, 2010). A capillary tube containing the test and donor mucus is placed into a test tube containing a small amount of the semen (male partner in one tube, donor sperm in another tube). Following incubation for 1–2 h, the motility, migration, and penetration of the sperm into the mucus are noted. The results are classified based on the numbers of sperm that penetrated into the mucus, the distance of passage into the mucus, and the time the sperm remained motile.

Presently, the simple assessment of the interaction between the sperm and cervical mucus using in vivo and in vitro methods is infrequently used, but nonetheless, these tests can provide useful information in evaluation of the infertile couple. Most recently, the role of the sperm–cervical mucus penetration tests, and the PCT have been questioned and remain controversial in the era of evidence-based medicine (Pavone et al., 2011) and the frequently used assisted reproductive procedures such as intrauterine insemination.

"In chaos, there is fertility"

Anaïs Nin

Introduction

Mammalian fertilization is a seemingly chaotic but exquisitely organized biological process that requires a delicate progression of events toward sperm and oocyte encounter at the fertilization site, located at the upper segment of the fallopian tubes (oviductal ampulla in nonhuman mammals). Therein, male and female gametes assemble to accomplish fertilization and to initiate embryogenesis.

In recent years, great steps have helped researchers to elucidate the innermost phenomena in this chaos, but there is still a long way to go. Sperm that have completed morphogenesis in the testis and maturation while they transit through the epididymis, are ejaculated and deposited in the female reproductive tract. In their journey to fertilization, they must undergo a complex series of changes collectively known as sperm capacitation to develop full fertilizing competence. At the fertilization site, sperm meet the cumulus oocyte complex (COC). The cumulus is a cellular structure composed of granulosa cells that protect the oocyte and help trapping high quality sperm required for fertilization. Afterward, sperm interact with the *zona pellucida* (ZP), an acellular matrix of glycoproteins that surrounds the oocyte and gives species-specificity to the interaction with the male gamete. Sperm that have undergone the acrosome reaction (AR) penetrate the ZP and reach the oocyte plasma membrane (oolemma), to which they bind and fuse, followed by nuclear decondensation (Yanagimachi, 2012).

The interest for the mechanisms that rule fertilization referred to ancient times, when Hippocrates (460–370 years BCE) argued that both men and women contributed to form the embryo. Later on, Aristotle (384–322 BCE) proposed that women provided fertile ground for the male seed to grow. By the 17th century, studies already recognized that men produce spermatozoa, as A. van Leeuwenhoek first described in 1667 the human sperm. Over 150 years later, in 1827, K. von Bare discovered eggs in canine and human ovaries and, in 1875, O. Hertwig described sea urchin zygote formation after sperm–oocyte fusion. The 20th century witnessed numerous advances based on many new experimental tools available to better study these events, among them optical and electron microscopy, antibodies and other biochemical tools, in vitro models and, more recently, cloning, stem cell technologies, molecular biology and gene manipulation, including transgenesis and gene knock out models. All of them played important roles toward understanding the molecular basis of fertilization and revolutionized modern biology. These tools have been available and used due to the contribution of numerous passionate researchers worldwide, among whom R. Yanagimachi stands out for his tireless, innovative, inspiring, and outstanding work about mammalian fertilization. Dr. Yanagimachi published over 300 outstanding reports using rodent models in several topics: sperm capacitation, the mechanism and site of acrosome reaction, in vitro fertilization (IVF), intracytoplasmic sperm injection (ICSI), cloning, among many breakthroughs in reproductive biology. Our humble and respectful tribute is dedicated to this outstanding pioneer scientist.

In 1978, human IVF finally broke through as a clinical practice with R. Edwards and P. Steptoe first living childbirth after an IVF, setting the bases for clinical infertility management, just as ICSI did in 1992 with G. Palermo. Currently, IVF and ICSI are worldwide standard procedures in clinical practice and tools used to unravel molecular mechanisms and identify molecules involved in sperm–oocyte interactions (Yanagimachi, 2012).

Based on the advances accomplished in the field of mammalian fertilization, a series of laboratory tests were developed in the last decades, aimed at evaluating human sperm fertilizing potential by mimicking some of the events that sperm have to overcome in their journey. A brief summary of the most relevant sperm–ovum interaction assays is summarized below.

Laboratory Evaluation of Sperm–Ovum Interaction

Sperm Interaction With the Cumulus Oophorus: The Hyaluronan Binding Assay

The first coating that sperm go through to reach the oocyte is the cumulus oophorus, a multilayered cell vestment composed of granulosa cells immersed in an extracellular matrix of hyaluronic acid (HA) (or hyaluronan), which grants the viscoelastic properties of this matrix. Sperm express HA receptors that bind to the cumulus. HA seems to play an important role during fertilization by selecting mature sperm with intact acrosomes and normal sperm morphology, minimal DNA fragmentation, and low frequency of chromosomal aneuploidies. These HA properties provided the basis for the hyaluronan binding assay (HBA) (Huszar et al., 2003).

Briefly, in the HBA a sperm suspension is placed in contact with a drop of suitable medium coated with HA, resulting in high quality sperm cells attached to the coated surface depicting vigorous tail movement, while unfit spermatozoa remain free. After sorting each population by transferring the unattached sperm into a new medium drop, a hyaluronan binding score (HBS) can be calculated as $HBS = (\text{bound sperm} / \text{total sperm}) \times 100$ (Nasr-Esfahani and Marziyeh, 2013) (Fig. 1). In a prospective study, the HBA test

Fig. 1 Hyaluronan binding assay. A sperm suspension is placed over a HA-coated spot. Spermatozoa with vigorous tail movement are located in the inner area of the droplet, while unfit spermatozoa remain free. The hyaluronan binding score (HBS) is calculated as $HBS = (\text{bound sperm} / \text{total sperm}) \times 100$. HBA is also a suitable assay to select high quality spermatozoa prior to ICSI, the denoted physiological ICSI (PICSI).

was helpful in distinguishing semen samples suitable for IVF or ICSI (Pregl Breznik et al., 2013). In a later study done on patients undergoing ICSI treatment, HBA results correlated with fertilization rates and biochemical pregnancy values but not with parameters from routine semen analysis and clinical pregnancy rates (Esterhuizen et al., 2015). HBA has been also found suitable to select high quality sperm prior to ICSI, the denoted physiological ICSI (PICSI); this way, a high quality sample is assured. In this regard, a meta-analysis reported in 2016 on seven studies and over 1400 cycles revealed that HBA performance prior to ICSI improved embryo quality and implantation rates, while no enrichment in fertilization and pregnancy rates was found. Moreover, an analysis of prospective studies only showed an improvement in embryo quality. Authors emphasized the need of more studies to determine the benefit of the procedure in patients treated with ICSI (Beck-Fruchter et al., 2016).

There are currently two commercial alternatives for the HBA, one from Biocoat, USA and another from MidAtlantic Diagnostics Inc., USA.

Laboratory Procedure

1. Sperm suspension preparation
 - a. Calculate sperm concentration using a counting chamber.
 - b. Add suitable sperm culture medium to adjust sperm concentration to $0.2 - 1 \times 10^6$ sperm cells/mL.
2. Hyaluronic acid coating
 - c. Place a 10–50 μL droplet of hyaluronic acid (HA) with sterile water (1:40) in a tissue culture dish and let it dry.
 - d. Wash the coated spots with 15–75 μL of suitable medium.
3. Binding assay
 - e. Replace the washing medium droplet with 50 μL of a sperm suspension containing $1 - 5 \times 10^4$ sperm cells. Incubate 5–10 min.
 - f. *Diagnostic purposes:* calculate HA-bound sperm cells, characterized by a vigorous tail movement without progressive motility (unbound motile spermatozoa move without restriction). Nonmotile spermatozoa are not taking into account for the HBA report.
Therapeutic purposes: Select and detach HA-bound sperm cells for ICSI procedure using the ICSI-injecting pipette, and inject into oocytes.
4. Scoring
 - g. Count the number of motile sperm bound and unbound to the HA matrix using a phase contrast microscope. HBA score (%) is calculated as the number of bound motile sperm divided by the total number of motile sperm (multiplied by 100). The sum of bound and unbound spermatozoa counted is expected in the range of 150–200 to achieve good assay precision.

Note: The WHO Manual (Fifth Edition) does not describe this test.

(Adapted from Nasr-Esfahani, M. H., Marziyeh, T. (2013). Sperm selection for ICSI using the hyaluronic acid binding assay. Methods in Molecular Biology 927, 263–268.)

Sperm Interaction With the Zona Pellucida: The Hemizona Assay and the Sperm Zona Binding Ratio Assay

The ZP is an extracellular glycoprotein matrix formed by the oocyte during growth. Four ZP proteins (ZP1–ZP4) have been characterized in humans. Sperm binding and penetration of the ZP is critical for successful fertilization. In 1976, a procedure was described to assess human sperm–oocyte interaction (Overstreet and Hembree, 1976). Even though this assay was originally designed to evaluate sperm penetration of human ZP, it also provided the basis for a sperm–ZP binding assay. 12 years later, two assays were reported. Firstly, Burkman et al. (1988) developed the hemizona assay (HZA). The procedure involves ZP microdissection into equal halves and incubation of each half with the same concentration of Control (fertile men) or Test sperm (a patient sample in a clinical set-up; control sperm treated with a specific agent in a basic research set-up) (Fig. 2A). The HZA results are expressed as the hemizona index (HZI), calculated as follows: $HZI = \text{number of bound sperm from the Test sample} / \text{number of bound sperm from the Control sample}$ ($HZI = 1$ in cases when Test sperm have the same binding ability as

Fig. 2 Sperm–ZP interaction assays. (A) Hemizona assay. Discarded unfertilized or nonliving inactivated human oocytes are cut by half, and each HZ is co-incubated with Control or Test selected-motile sperm placed in culture medium droplets. After a 4-h incubation period, loosely bound sperm are removed by pipetting and the number of sperm bound to each hemizona is recorded. (B) Sperm zona binding ratio assay. Control and Test selected-motile sperm are incubated in culture medium droplets containing fluorescent dyes. Discarded unfertilized or nonliving inactivated human oocytes are co-incubated with a mix of both fluorescent selected-motile suspensions. After a 4-h incubation period, loosely bound sperm are removed by pipetting and the number of each fluorescent type sperm bound to the ZP is recorded.

Controls). Secondly, Liu et al. (1988) reported the development of a competitive sperm–ZP binding assay called sperm zona binding ratio (SZPB ratio) assay. The assay involves Control sperm labeling with a fluorescent dye (e.g., tetra-methylrhodamine B isothiocyanate) and Test sperm labeling with another fluorescent dye (e.g., fluorescein isothiocyanate), and incubation of both sperm samples with an inactivated human denuded oocyte (Fig. 2B). The number of sperm from the Test and Control cell suspensions bound to the same ZP are counted and reported as a ratio. Few or no sperm bound to the ZP is usually indicative of a sperm defect(s). The SZPB ratio assay uses a threshold similar to that of the HZA.

Both tests have shown to highly predict IVF outcome, as revealed from individual studies and from meta-analyses. Prospective clinical studies reported a cut-off HZI value of 30 as predictive of IVF outcome. In intrauterine insemination procedures, an HZI <30 was associated with a lower pregnancy rate compared with patients with HZI >30, showing a 90% sensitivity and a 78% specificity in cases of male factor infertility, although it was not found useful in couples with unexplained infertility (reviewed in Oehninger et al., 2014).

While the procedure by Liu does not require a micromanipulator to dissect the ZP, it does need a fluorescence microscope. Moreover, since sperm–ZP interaction is species-specific, only human ZP can be used for the abovementioned assays. Despite the difference in their methodologies, both assays include an internal positive control; this is highly relevant, considering that oocytes used in the assay may have abnormalities in their ZP-binding properties. Oocytes used are obtained from failed IVF procedures, as well as from ovaries surgically removed or from autopsies, and inactivated during storage in salt-based solutions.

Studies using the sperm–ZP interaction assays revealed the ability of the oocyte matrix to select sperm with normal morphology. Based on these observations, researchers have proposed the use of a simple and inexpensive method of sperm binding to the ZP of immature sibling oocytes as a procedure to select high-quality sperm for ICSI procedures (Liu, 2011). Controlled clinical trials in larger numbers of subjects are needed to confirm these findings.

Laboratory Procedure: The Hemizona Assay

1. Sperm preparation
 - a. Wash the sperm suspension two times with suitable medium.
 - b. Allow the washed sperm to swim-up for an hour.
2. Hemizonae preparation
 - c. Grasp a discarded or nonliving oocyte with a holding pipette and cut by half with a microscalpel blade.
 - d. Dislodge the ooplasm by pipetting.
3. Hemizona assay
 - e. Adjust the sperm concentration to 10^4 sperm/mL.
 - f. Place two 50 μ L droplets of the sperm suspension under oil (Control and Test samples).
 - g. Add one hemizona of a pair to each droplet and incubate for 4 h.
 - h. Rinse each hemizona by vigorously pipetting them in washing medium.
4. Scoring
 - i. Count the number of motile sperm bound to each hemizona matrix using a phase contrast microscope. The HZI score is calculated as the ratio between the number of bound motile Test sperm divided by the number of motile Control sperm (multiplied by 100 when expressed as percentage).

Note: While the WHO manual (4th Edition) described the sperm–ZP binding assays, the 5th Edition only briefly refers to these tests.

(Adapted from Burkman, L. J., Coddington, C. C., Franken, D. R., Kruger, T., Rosenwaks, Z., Hogen, G. D. (1988). The hemizona assay (HZA): Development of a diagnostic test for the binding of human spermatozoa to human hemizona pellucida to predict fertilization potential. Fertility and Sterility 49, 688–695.)

Sperm Acrosome Reaction: The AR Tests (ZIAR and ARIC)

The AR is an exocytotic event that must take place before the spermatozoon penetrates the oocyte vestments to accomplish fertilization. The AR involves fusion of the sperm plasma membrane and the outer acrosomal membrane, exposure of the inner acrosomal membrane and acquisition of fusogenic properties of the plasma membrane at the equatorial segment. Despite the long time evidence favoring the occurrence of AR once sperm attached to the ZP, findings using genetically modified rodents indicate that the physiological AR may occur prior to sperm–ZP contact.

The incidence of spontaneous AR in ejaculated human sperm is low (~5%–10%), and it increases after capacitation and AR induction. There are several physiological agents (e.g., follicular fluid, progesterone, ZP glycoproteins) that induce AR. Since Ca^{++} influx is one of the AR initiating events, Ca^{++} ionophores (e.g., ionomycin and A23187) can trigger this event, but results may not relate to those obtained from the ZP-induced AR. The sperm acrosomal status can be assessed by microscopy or flow cytometry with fluorescently labeled lectins that bind to acrosomal contents, such as *Pisum sativum* agglutinin or, alternatively, antibodies against acrosomal proteins (WHO, 1999; WHO, 2010) (Fig. 3).

The ZP-induced AR (ZIAR) assay can be done by incubating sperm with acid-solubilized ZP, assessing the results using fluorescent dyes and calculating the sperm response as the difference between the ZIAR (stimulated) and the spontaneous (unstimulated) AR results. Unfortunately, this test is limited by the restricted availability of human ZP. The AR after ionophore challenge (ARIC) is calculated using the same criteria as the ZIAR. A clinical cut-off value of 15% has been reported for both assays. Patients may have

Fig. 3 Induced acrosome reaction assay. A selected-motile sperm suspension is exposed to capacitating conditions and Ca⁺⁺ ionophore A23187. Ionophore-exposed spermatozoa are incubated with [FITC]-PSA fluorescent dye for 1 h, and acrosome status is recorded: acrosome-intact sperm, acrosome-reacted sperm or other patterns.

two types of AR defects: premature AR (> 20% of spermatozoa exhibiting spontaneous AR) or insufficient AR (poor response to AR stimuli). Several studies have shown that ZIAR and ARIC can help predicting fertilization at conventional IVF, but the predictive values vary among studies (reviewed in Sigman et al., 2009; Oehninger et al., 2014).

The AR allows sperm penetration of the ZP and fusion to the oolemma. Thus, determining the acrosome reacting ability is important in the diagnostic and therapeutic approach to couples undergoing conventional assisted reproductive technology treatment. In cases of a poor acrosome reaction, ICSI therapy may be advised. Unfortunately, since most centers indicate ICSI as primary ART procedure, the AR assay is rarely used.

Laboratory Procedure: Induced Acrosome Reaction Assay

1. Sperm preparation
 - a. Calculate sperm concentration after semen liquefaction and washing.
 - b. Incubate 1×10^6 motile sperm for 3 h in sperm capacitating medium.
2. Sperm induction of acrosome reaction and staining
 - c. Add 10 μ M of A23187 calcium ionophore (alternative: *zona pellucida*) and incubate for 15 min to induce acrosome reaction.
 - d. Stop the reaction by adding 100 μ L of 3% (v/v) glutaraldehyde or 70% (v/v) ethanol.
 - e. After washing, stain fixed sperm placed onto microscope slides using fluorescent lectins, such as *Pisum sativum* agglutinin, coupled to fluorophores, for example, Fluorescein IsoThioCyanate, as [FITC]-PSA for an hour at 4°C.
 - f. Wash each slide with water and mount in ethanol-soluble medium.
3. Scoring
 - g. Assess the percentage of acrosome-reacted sperm (Test and Control): View the slide with fluorescence optics at 400 $\times$ magnification with oil immersion at 450–490 nm excitation.
 - h. Categories:
 - Acrosome-intact: sperm with brightly fluorescent head (half or more).
 - Acrosome-reacted: sperm with poor fluorescent signal at the equatorial segment or none at all.
 - Others (Acrosome-reacting): sperm with “patchy” fluorescent signal in the acrosomal cap (not shown in Fig. 3).

Note: The WHO Manual (Fourth and Fifth Edition) present a detailed protocol for the assessment of the sperm acrosomal status and the ionophore induced AR. (Adapted from WHO Manual, Fifth Edition).

Fig. 4 Sperm penetration assay. (A) Standard and ionophore-induced procedures for sperm treatment. A selected-motile human sperm suspension is capacitated for 18–24 h. (1) Alternatively, capacitated spermatozoa are exposed to Ca^{++} ionophore A23187 for 1 h. Meanwhile, hamster COC are treated with hyaluronidase (to remove cumulus cells) and trypsin (to remove the ZP). Capacitated or Ca^{++} ionophore A23187-exposed sperm are incubated with ZP-free oocytes for 3 h, after which loosely bound sperm are washed out, and oocytes are mounted to score the % of oocytes with at least one decondensed sperm. (B) Modified procedure using Test-Yolk buffer (TYB) conservation. A semen sample is mixed with TYB and stored at 4°C for 42 h. Then, the TYB is removed and sperm are resuspended in a suitable medium (e.g., BWW) at 37°C (heat shock). Hamster COC are treated with hyaluronidase and trypsin. Sperm recovered after the heat shock are incubated with ZP-free oocytes for 2.5 h, after which loosely bound sperm are washed out, and oocytes are mounted to score the number of decondensed sperm heads in each oocyte. A parallel assay is done with the control semen sample (fresh or previously cryopreserved).

Sperm Interaction With the Oolemma: The Zona-Free Hamster Egg Sperm Penetration Assay

Sperm that have completed the AR, penetrate the ZP, and reach the perivitelline space. There, they come in close contact, bind and fuse, to the oolemma. As mentioned previously, the ZP provides species specificity, thus preventing cross-species fertilization. Investigations done back in 1976 by Dr. R. Yanagimachi and coworkers demonstrated the promiscuous behavior of hamster oocytes. In their study, they showed that ZP removal was sufficient to allow fusion and nuclear decondensation in the cytoplasm of sperm from several species, including humans. Based on these observations, the report described the development of the sperm penetration (SPA) assay, also known as the zona-free hamster egg–human sperm penetration assay (ZP-free SPA), using denuded hamster ova.

This test is one of the most sensitive measures of sperm function available, since sperm that had undergone the AR and penetrated the ZP, reach the perivitelline space and bind and fuse to the oolemma. Despite the fact that SPA does not measure sperm interaction with the ZP, it evaluates sperm ability to undergo the AR and provides information on the fusogenic nature of capacitated sperm plasma membrane at the equatorial segment and the ability to accomplish nuclear decondensation in the oocyte's cytoplasm. Depending on the protocol, it also measures the spermatozoa's ability to capacitate under the conditions assayed.

Conventional SPA relies on the occurrence of spontaneous AR in populations of sperm incubated in vitro for prolonged time periods, depicting false negative results, with failure in the SPA but success in the IVF procedure. Consequently, a modification of the standard procedure was introduced, using calcium ionophore-stimulated sperm to increase the amount of acrosome-reacted sperm and reduce the false negatives. In both classical and modified protocols, the percentage of ova that show at least one decondensed sperm head is determined, being positive when at least 10% and 50% penetrated oocytes are scored, respectively (Fig. 4). Also, a modified SPA procedure was developed, named “the optimized SPA.” The protocol introduces a modification on sperm handling to produce a vast subpopulation of acrosome-reacted sperm cells, which is accomplished by a combination of sperm storage at 4°C in a solution enriched in egg-yolk components that intercalate in the sperm plasma membrane followed by a heat shock procedure that induces a massive sperm AR. This protocol modification resulted in oocyte polyspermy in control sperm suspensions, reducing false negatives and consequently increasing assay sensitivity. Using this protocol, a lower limit of positive assay was established at five decondensed sperm heads per oocyte, defined as sperm capacitation index or SCI (reviewed by Lamb, 2010).

A report published in 2013 compared the results of the SPA and HZA. On one hand, the SPA showed wide parameters to predict IVF outcome, most likely because of differences in methodology and cut-off values used in each study. On the other hand, HZA methodology correlated well with IVF outcome and demonstrated better positive/negative predictive power. The report suggested the use of HZA in a sequential fashion with semen analysis and potentially other bioassays in an IVF setting (reviewed by Oehninger et al., 2014).

Nowadays, the SPA is rarely practiced in the clinical andrology laboratories, but it is still used for research focused on unrevealing the molecular basis of sperm–oolemma binding and fusion. Interestingly, despite its use to predict failure of sperm decondensation in ICSI using a variation of the procedure (reviewed by Lamb, 2010), the SPA test has not expanded in the ICSI era.

Laboratory Procedure: Sperm Penetration Assay

1. Sperm preparation
 - 1.1. Standard procedure
 - a. Subject the semen sample to motile sperm selection by density-gradient centrifugation or swim-up procedures.
 - b. Adjust the concentration of the selected sperm suspension to 1×10^6 sperm/mL.
 - c. Incubate the sample under capacitating conditions for 18–24 h in 0.5 mL of suitable medium.
 - 1.2. Optional incorporation of calcium ionophore A23187
 - d. Adjust the concentration to 5×10^6 sperm/mL.
 - e. Incubate separate sample aliquots with 1.25 and 2.5 μ M of calcium ionophore A23187 for 3 h.
 - f. Wash and adjust the concentration to 3.5×10^6 sperm/mL.
 - 1.3. Optional Test-Yolk Buffer (TYB) conservation and processing
 - g. Within the hour of collection, dilute the semen samples in tubes with an equal volume of TYB at room temperature.
 - h. Immerse the tubes in room temperature water and place them in a refrigerator.
 - i. Remove the TYB supernatant after 42 h and dilute in suitable medium at 37°C.
 - j. Retrieve motile sperm from the top third of the supernatant and adjust the concentration to 3.5×10^6 sperm/mL.
 - k. Place a 50 μ L droplet of the suspension into a Petri dish.
2. Oocyte preparation
 - a. Inject immature hamsters with 30 IU of PMSG intraperitoneally.
 - b. Inject the same hamsters with 40 IU of hCG after 48–72 h.
 - c. Sacrifice the hamsters 18 h after hCG injection.
 - d. Recover the COC by extracting and dissecting the oviduct.
 - e. Place the retrieved COC into droplets containing hyaluronidase (1 g/L) for 10 min to separate the oocyte from cumulus cells.
 - f. Rinse the oocytes and place them in droplets of suitable medium.
 - g. Treat the oocytes with trypsin (1 g/L) for 1 min to remove the ZP.
 - h. Wash the oocytes three times with suitable medium.

3. Sperm penetration assay:

- a. Place up to five oocytes per droplet and co-incubate them for 3 h.
- b. Thoroughly wash the oocytes to remove loosely bound spermatozoa.
- c. Place small droplets with washed oocytes on microscope slides and cover them with coverslips held by small wax-petroleum jelly pillars.
- d. Calculate the number of decondensed sperm heads per oocyte, and the percentage of penetrated oocytes by phase-contrast microscopy examination.

Note: The WHO Manual (Fourth and Fifth Edition) present a detailed protocol for the ZP-free hamster egg sperm penetration assay.

Concluding Remarks

Sperm–oocyte interaction has been extensively studied in the last 50 years, and several approaches have been used to contribute to understanding the molecular basis of fertilization. The tests described above were developed in the last decades in parallel with in vitro fertilization and early embryonic transfer procedures. Being aware of the limited predictive value of semen analysis on sperm fertility potential, researchers developed these set of in vitro sperm–ovum interaction assays. These tests were also used to identify entities involved in the molecular mechanisms of fertilization. With the advent of ICSI, the evaluation and treatment of the infertile male dramatically changed. The procedure requires a single live sperm to be injected in the oocyte cytoplasm, bypassing all events tested to predict fertility potential. Although it was initially indicated for severe male factor infertility, ICSI was soon applied to all pathologies. ICSI offspring health is now being evaluated, finding abnormalities that may be related to the lack of an adequate sperm selection procedure.

Authors still believe that the abovementioned tests may be beneficial toward the selection of the appropriate ART procedure, to avoid the use of ICSI as a sole procedure to treat infertility. In addition, they may be used as tools to select sperm for ICSI, specifically, the HBA and the sperm–ZP binding assays. While the HBA is based on a reagent, the ZP–sperm assays require human ZP, which limits the assay usage. The research in this field should turn toward a large production of recombinant bioactive ZP–glycoproteins expressed in heterologous systems and couple them to a solid phase platform, replacing the scarce natural source. These “ZP-like” structures will then be used to assess sperm-binding potential and eventually to recover bound sperm for microinjection purposes. Finally, these assays should be used in a basic set-up to identify molecular biomarkers of sperm–ovum interaction that will become a powerful complement in the future Andrology-patient workout. There is still a lot of work ahead.

Laboratory Evaluation of Sperm Chromatin Structure

Luke Simon and Douglas T Carrell, University of Utah School of Medicine, Salt Lake City, UT, United States

© 2018 Elsevier Inc. All rights reserved.

What Is a Normal Sperm Chromatin?

In somatic cells, the DNA is bound to histones in a loose loop like manner to facilitate transcriptional activities. However, in sperm, transcription is inactive and the DNA is organized in a specific tight-coiled manner with the help of protamines (Oliva, 2006). The exchange in nuclear proteins allows a very tightly packaged chromatin, which facilitates the sperm head into streamline structure and also protect against oxidative damage. The chromatin is packed in a very precise fashion that allows the embryonic genome to easily access the genetic information soon after fertilization (Nanassy and Carrell, 2008). The sperm of fertile men is characterized to have an intact DNA, organized in a compact fashion and is capable of decondensation soon after fertilization.

How Does the Sperm Chromatin Get Damaged?

Number of factors has been reported to induce sperm DNA/chromatin damage. The main factor for chromatin damage is oxidative stress, which is an increase in the production of free radicals or reactive oxygen species (ROS) as a byproduct of normal cellular mechanism (Aitken and De Iuliis, 2007). It is observed that patients with leukocytospermia are showed to have high levels of oxidative stress. Leukocytospermia is a condition where the level of leukocytes increase in the semen as a result of genital tract infection or inflammation. When ROS comes in contact with sperm DNA, it can result in a base modification or single strand break. Cigarette smoking is showed to induce oxidative stress by overproduction of ROS (Aitken and De Iuliis, 2007). Patients with leukemia, testicular cancer, diabetic and Hodgkin's disease are showed to have increased level of sperm DNA damage. Treatments for diseases using cytotoxic drugs and radiation therapy could also affect the sperm DNA integrity.

Environmental and occupational exposures to chemicals, radiation and pesticides are known to increase sperm DNA damage. Studies have showed that intensive physical exercise could result in scrotal heating, inducing sperm chromatin damage (Aitken and De Iuliis, 2007). Defects in the spermatogenetic process such as abnormal chromatin packing may also result in sperm DNA damage. Approximately 85% of the histones are replaced to protamines, but high level of histone may suggest abnormal chromatin packaging and nuclear maturity defects (Oliva, 2006). In addition, abnormal chromatin packaging may render the sperm vulnerable to oxidative stress mediated DNA damage.

Finally, laboratory treatment and protocols are also known to affect chromatin integrity. For example, sperm preparation technique such as density gradient centrifugation (commonly used during assisted reproduction procedure) is showed to generate ROS. Another well-known example is the sperm cryopreservation protocols (where sperm is stored in liquid nitrogen for future use) is also showed to induce DNA damage (Thomson et al., 2009).

Evaluation of Sperm Chromatin Integrity

The stability of sperm chromatin/DNA integrity is important for a successful conception in vivo as well as in vitro. Assisted reproductive treatment (ART) outcomes such as, fertilization rates, embryo quality and development rates, implantation rates, clinical pregnancy outcomes, miscarriage and live birth rates are showed to be associated with sperm DNA damage. Advances in molecular tools have resulted in the development of assays that could measure the level of DNA damage in each sperm or the percentage of DNA damaged sperm in an ejaculate. The ability of such assays to accurately estimate the level of sperm DNA damage depends on its principle and biological properties of these assays. The available assays that evaluate sperm DNA integrity can be broadly classified into two types, direct and indirect methods. The direct method includes, terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) assay, in situ nick translation assay and the comet assay, and the level of DNA damage could be measured in individual sperm. The indirect method of assays included sperm chromatin structure assay (SCSA) and sperm chromatin dispersion (SCD) assay, these methods measure the susceptibility of DNA to be damaged. Some staining methods are commonly used to evaluate the nuclear proteins (histones and protamines) packaging in sperm, such as aniline blue assay, toluidine blue assay, and chromomycin A₃ assay. These staining methods measure the compaction of the sperm chromatin structure and nuclear maturity, and serve as indirect methods to measure chromatin integrity. These direct, indirect and staining methods have been frequently used in andrology research to evaluate a correlation between sperm DNA integrity with male infertility. Recent evidence suggests that the direct method of sperm chromatin evaluation assay is more closely associated with male infertility and, therefore, researchers have suggested that these assays should be introduced into the routine andrology laboratory diagnosis (Simon et al., 2011).

Comet Assay

The comet assay, also known as single cell gel electrophoresis is one of the simplest methods to measure sperm DNA integrity by quantifying the single and double strand breaks. The principle of the assay is that the sperm nuclear DNA is separated in the electric field based on their charge and size which can be viewed using a fluorescent stain that can bind to DNA. During the comet assay, the intact DNA remains in the comet head, whereas short fragments of DNA strands migrate into the tail (Singh et al., 1988). The resulting images under the microscope resembles a comet, consisting of a head and tail (see Fig. 1). The amount of DNA damage in the sperm is directly proportional to the extent of DNA in the comet tail. In addition, the comet assay also measures the diameter of the comet head, olive tail moment and the comet tail length, etc., as these parameters are also associated with sperm DNA damage.

The comet assay is being used to assess DNA damage in a number of cell types including sperm and in a wide range of studies. The methodology of the assay involves the following steps. First, the sperm cells are fixed in agarose gel and treated with detergents to remove the cell membrane. Then the nuclear proteins are removed, which help in the decondensed of sperm DNA. The naked DNA is now subjected to electrophoretic, where in the electric field the DNA fragments containing negative charge migrates towards the positive electrode through the agarose. Following electrophoresis, the DNA is stained using fluorescent dyes and visualized using fluorescence microscopy. The comet assay can be performed in a neutral or alkaline environment: in the neutral condition (pH: 7) only DNA with double strand breaks are measured, while in the alkaline condition (pH: 13), the double stranded DNA is unwound into single strands and hence both single- and double-strand breaks are measured (Singh et al., 1988).

Advantages of the Comet Assay

The comet assay is a cheap and one of the most sensitive techniques available to measure sperm DNA damage. The level of sperm DNA damage measured by the comet assay is closely associated to other direct method such as TUNEL assay (Shamsi et al., 2008). The comet assay can be used to measure DNA damage in a variety of cell types, including sperm. The assay requires only a few of cells to perform the procedure. The data is measured using a software and hence its more precise and less prone to experimental bias. DNA damage measured by the comet assay is closely associated to male infertility and to various end points of ART outcomes (Simon et al., 2017).

Limitations of the Comet Assay

The comet assay lacks a standardized protocol to measure DNA damage in sperm, which makes it difficult to fully understand and relate the results from different research groups (Tarozzi et al., 2007). The assay is known to induce damage at the alkaline labile sites and hence it is difficult to discriminate between endogenous DNA damage with that of induced DNA breaks. When measuring DNA damage in somatic cells, presence of residual RNA could increase the background intensity and affect the results. The assay is also criticized for underestimation of DNA damage due to entangling of DNA strands. Incomplete chromatin decondensation in sperm, could reduce the level of DNA strand breaks to be revealed (Shamsi et al., 2008). Overlapping comet tails reduces the accuracy of the assay. Smaller tail fragments are lost in the agarose gel or too small to be visualized under the microscope. The assay is extremely laborious and is known to have high level of inter-laboratory variation.

Sperm Chromatin Structure Assay (SCSA)

The SCSA is the largest commercial available test to detect sperm DNA damage and was first reported in 1980 (Evenson et al., 1980). The assay protocol includes acid denaturation of sperm chromatin followed by acridine orange staining method and the intensity of the fluorescence is measured by a flow cytometer to determine sperm with DNA damage from that of normal sperm. The principle of SCSA is that the acridine orange stain binds to double stranded DNA to emit green fluorescence and the same stain binds to single

Fig. 1 Sperm DNA integrity measured by the alkaline comet assay: (A) sperm with high DNA integrity, (B) sperm with low DNA integrity exhibiting a typical “comet tail.”

stranded DNA to emit red fluorescence. Therefore, during acid denaturation of sperm chromatin, the separation of double stranded DNA into single strand DNA and such separation initiates at the site of the single and double strand breaks. The extent of DNA damage in the cell is determined by measuring the metachromatic shift from green fluorescence to red fluorescence after the acid treatment (Evenson et al., 1980). Therefore, normal cells will emit green fluorescence, while the DNA damaged cells will emit red fluorescence. The most important output parameter of SCSA is the DNA fragmentation index (% DFI), which represents the population of cells with DNA damage.

SCSA is an indirect method to measure DNA damage as it measures the susceptibility of sperm DNA to denaturation. Due to use of flow cytometry, it is possible to measure large number of sperm per sample making the technique highly reproducible. SCSA also measures highly DNA stainable (HDS) cells, which are described as the sperm population with increased accessibility of double-stranded DNA to the dye, mainly due to abnormalities in the replacement of histones with protamines (Evenson and Jost, 2000).

Advantages of SCSA

Sperm DNA damage measured by SCSA is known to be more constant over a longer period of time when compared with the traditional semen parameters. The consistency of the test makes it useful in most epidemiological studies (Shamsi et al., 2008). Freezing of semen samples does not affect the test, which allows samples to be batched for convenience or could be used in multi-center trials. The assay determines the percentage of sperm with DNA damage. Several clinical studies have shown its usefulness in associating the level of DNA damage measured by SCSA with male infertility. It is simple and rapid assay to analyze thousands of sperm. Researchers have found a threshold value of 30% DFI and 15% HSD above which men are likely to be infertile (Evenson and Jost, 2000). Several clinical studies have shown its usefulness in associating SCSA parameters with ART outcomes.

Limitations of SCSA

The SCSA does not give information about the extent of DNA damage in individual sperm. The assay requires expensive equipments for analysis. The assay protocol especially the acid denaturation step is time sensitive. DNA damage measured after density gradient centrifugation using SCSA is not predictive for ART outcomes (Shamsi et al., 2008). Sperm chromatin is highly coiled in nature, therefore absence of DNA decondensation step underestimates the level of DNA damage in sperm, as the acid denaturation occurs only at the periphery of the sperm nucleus.

Terminal Deoxynucleotidyl Transferase-Mediated dUTP Nick End Labeling (TUNEL) Assay

TUNEL assay is a direct method of DNA damage measurement. It is widely known to quantify DNA damage in somatic cells and can be efficiently used in sperm. The assay incorporates deoxyuridine triphosphate (dUTP) at single and double strand DNA breaks in a reaction catalyzed by the template-independent enzyme, terminal labels deoxynucleotidyl transferase (Gorczyca et al., 1993). The incorporated dUTP are labeled with fluorescent markers and hence the breaks can be quantified by flow cytometry or fluorescent microscopy. The TUNEL assay resembles the in situ nick translation assay in a number of technical aspects, but the template-independent enzyme used here helps to identify both single and double strand DNA breaks. The sperm DNA damage, measured by TUNEL assay, has a good stability with time and it is possible to measure baseline damage in both fertile and subfertile men (Sergeie et al., 2005). Sperm DNA fragmentation measured by the TUNEL assay is a valuable indicator of male fertility status and has been demonstrated to predict ART outcomes.

Advantages of TUNEL Assay

The assay has a simple protocol to simultaneously detect both single and double strand DNA breaks. Similar to SCSA freezing sperm samples does not affect the results of TUNEL assay. The popularity of TUNEL assay is justified by good quality control parameters, and low intra and inter observer variability. TUNEL assay can be performed using both fluorescent and light microscopy, depending on the type of labeling method used to visualize DNA breaks (Shamsi et al., 2008). The fluorescence labeling technique eliminates the problems associated with dye fading which occurs during conventional microscopic method, thereby giving the technicians more time to analyze a larger subset of samples. The coupling of the TUNEL assay with flow cytometry makes it possible to evaluate thousands of sperm in a short period of time, thus enhancing the accuracy and reproducibility of the technique.

Limitations of TUNEL Assay

TUNEL assay is not programmed to quantify the magnitude of DNA damage within a single cell, it only estimates the number of cells with DNA damage in a population of cells, termed as TUNEL positive cells (Shamsi et al., 2008). The light microscopy version of TUNEL assay is simple but the background staining decreases the efficiency of this method. The fluorescence labeling protocol requires highly sophisticated and expensive instruments. Due to a lack of useful threshold values and standardized protocol, the assay unreliable for routine clinical use (Simon et al., 2014). Extensive training is required for laboratory technicians to obtain a consistent and reproducible data. Due to the unique nature of the sperm chromatin organization and absence of a decondensation

step during the assay protocol, the TUNEL assay has been criticized as possibly only labeling the periphery of the sperm nucleus, and hence possibly underestimating the level of sperm DNA damage.

In Situ Nick Translation

The in situ nick translation (ISNT) assay is a modified form of TUNEL which quantifies the incorporation of biotinylated deoxyuridine triphosphate (dUTP) at single-stranded DNA breaks in a reaction that is catalyzed by the template-dependent enzyme, DNA polymerase I ([Irvine et al., 2000](#)). Unlike the TUNEL assay which utilizes template independent end labeling, nick translation can only be used to detect single strand DNA breaks. INST is a direct method of DNA damage measurement.

Advantages of ISNT

The assay identifies sperm that contain low and variable levels of endogenous DNA damage and is positively associated with protamine deficiency. Due to the efficiency of the DNA polymerase enzyme which is used in the assay, the single strand nicks are incorporated with labeled dUTP and hence a low levels of fluorescence in the sperm can be detected ([Shamsi et al., 2008](#)).

Limitations of ISNT

The clinical value of the nick translation assay is severely limited because no correlation has been proven with fertility outcomes during in vitro and in vivo studies. Other assays such as TUNEL and comet assays show better sensitivity when compared with ISNT assay, as ISNT assay measures only single strand DNA breaks. Furthermore, single strand breaks can be more easily repaired by the embryo when compared to double strand DNA breaks and hence the value of assay as a diagnostic tool is limited ([Shamsi et al., 2008](#)).

Sperm Chromatin Dispersion (SCD) Assay

The SCD assay, also known as Halo test, has been described as a simple and inexpensive method to analyze sperm DNA damage. It is based on the principle that sperm with fragmented/damaged DNA fail to produce the characteristic halo ([Fernandez et al., 2003](#)). The methodology of the test includes the following steps. First the sperm is fixed in an agarose matrix on a glass slide and allowed to solidify. The agarose matrix holds the sperm on a slide in a suspension-like environment. The slides are then treated with detergent to remove the cell membrane and nuclear proteins, followed by acid denaturation of the double stranded DNA. The removal of nuclear proteins results in nucleoid with a central core and a peripheral halo of dispersed DNA loops, which can be viewed using a DNA stain. The sperm nuclei with increased DNA damage produce very small or no halos, whereas normal sperm is able to release their DNA loops forming large halos ([Fernandez et al., 2003](#)).

Advantages of SCD Assay

This assay is a simple, fast, highly reproducible and inexpensive technique, where DNA damage as reflected by the size of the halos can be accurately determined. This assay does not rely on color or fluorescence intensity hence it is simple to analyze with light microscopy. The assay does not require the use of any complex and expensive instruments, as it can be carried out with equipment available in the andrology laboratory (such as a light microscope). The test endpoints are non-dispersed or dispersed halos, which can be easily distinguished by a laboratory technician. Therefore, the SCD assay has a potential to be routine used in the clinical laboratory for sperm chromatin evaluation ([Shamsi et al., 2008](#)).

Limitations of SCD Assay

The assay has been reported to have low-density nucleoids which are fainter with less contrasting images. Frequently, the peripheral limit of the halo, where the chromatin is even less dense, may not be accurately discriminated from the background. All the halos are not in the same plane hence, the use of software to analyze can result in misreading due to unfocused halos ([Shamsi et al., 2008](#)). More importantly, sperm tails are not preserved during the assay protocol; therefore, discriminating sperm from other contaminant cells is problematic. Another major disadvantage this assay is the lack of correlation between halo size with male fertility status and ART outcome, making this assay less suitable for diagnostic purposes.

Aniline Blue Assay

The aniline blue staining method is commonly used to study the chromatin maturity or chromatin compaction of sperm, as it is able to detect sperm chromatin defects related to their nucleoprotein content ([Auger et al., 1990](#)). The stain specifically binds to

histones and leaving the protamines unstained. Specifically, the stain binds to the amino acids region rich in lysine. Histones are basic proteins and are rich in lysine residues, whereas protamines are arginine and cysteine rich proteins. During spermatogenesis, the histones in the sperm nucleus are replaced to protamines. Approximately, 15% of the histones are kept in the nucleus at specific regions of the sperm chromatin. Therefore, increase in aniline blue staining correspond to increase in the level of histone retention, such sperm are considered as immature sperm with defective chromatin organization, whereas mature protamine-rich nuclei remain unstained.

The methodology of aniline blue stain is simple. Briefly, sperm sample are smeared on glass slides and air-dried. Sperm is then fixed with 4% formaldehyde solution and then stained with 5% aqueous aniline blue solution mixed with 4% acetic acid (pH: 3.5) for 5 min. The excessive stain is then removed by introducing the slide to a stream of water. The slides are air-dried and viewed under a light microscope.

Advantages and Limitations of Aniline Blue Assay

This staining method is very simple, inexpensive, rapid and the stained sperm can be viewed under a light microscope. The stain is able to differentiate between histones and protamines in sperm nucleus and hence it is able to identify immature sperm. The aniline blue staining method is an indirect method to study sperm chromatin status as the stain binds to chromatin bound histones but not to sperm chromatin.

Toluidine Blue Assay

Toluidine blue is a basic nuclear stain and is commonly used for metachromatic and orthochromatic staining of chromatin. This stain binds to the phosphate residues of sperm chromatin structure at places where the chromatin is free and not bound to histones or protamines. Therefore, the stain measures the availability of the free sperm chromatin DNA phosphate residues, which depends on both the protamination and DNA integrity of sperm. Dark purple stained nucleus correspond to abnormal sperm whereas, light blue stained nucleus correspond to normal sperm (Tsarev et al., 2009).

The methodology of toluidine blue staining is simple and consists of the following steps. Sperm samples are smeared on glass slides and then air-dried. The slides are then fixed with freshly prepared 96% ethanol–acetone (1:1 ratio) for 30 min and hydrolyzed with 0.1 N HCl for 5 min, and thoroughly rinsed with water. The slides are then stained with 0.05% toluidine blue stain prepared with 50% McIlvain's solution (citrate phosphate buffer, pH: 3.5) for 10 min. Slides were then rinsed briefly in water, dehydrated in tertiary butanol, cleared with xylene and mounted with DPX (water-insoluble embedding medium for histological preparations).

Advantages and Limitations of Toluidine Blue Assay

This staining method is very simple, inexpensive, rapid and the stained sperm can be viewed under a light microscope. The stain is able to differentiate sperm with abnormal chromatin packing from sperm with normal chromatin structure. The stain is very stable and hence it is a reliable method for assessing the sperm chromatin. The toluidine blue staining method is an indirect method to study sperm DNA integrity as the stain binds to regions of chromatin not bound to histones or protamines.

Chromomycin A₃ Assay

The chromomycin A₃ stain is used to identify sperm nucleus with poor chromatin organization. The stain binds to guanine–cytosine specific residues, which are present at the minor groove of the sperm chromatin. This stain and protamines compete for the same binding sites in the sperm chromatin. Therefore, high chromomycin stained sperm is a strong indicator of sperm with abnormal protamine packing (Iranpour et al., 2000).

The methodology of chromomycin staining method includes the following steps. Sperm samples are smeared on a glass slides and then air-dried. The sperm is then fixed in methanol-glacial acetic acid (3:1 ratio) for 20 min and then air-dried. The slides are then stained with 100 µL of chromomycin staining solution (0.25 mg/mL in McIlcaine buffer, pH: 7.0 containing 10 mM MgCl₂). The slides are then rinsed with PBS and mounted with buffered glycerol (1:1 ratio of PBS-glycerol). Under a fluorescent microscope, the sperm stained bright yellow are abnormal sperm (chromomycin positive), while the sperm stained dull yellow are chromomycin negative, or sperm with normal chromatin.

Advantages and Limitations of Chromomycin A₃ Assay

This staining method is simple, inexpensive and rapid but it requires complex instrumentation, such as a fluorescence microscopy and qualified technician to perform the experiment. Based on the stain intensity sperm can be differentiated into sperm with abnormal and normal chromatin packing, but the assay is criticized to have a low degree of separation. The stain is not stable for a long period of time and hence the slides should be read immediately or it can be refrigerated overnight. This is an indirect method to study sperm chromatin integrity as the assay reveals the amount of sperm chromatin not bound to protamines.

Conclusions

Simple and effective assays are available to assess sperm chromatin. Assays can distinguish single and double strand DNA strand breaks, as well as the protamination process. Standardization of assays and the establishment of consensus assays has not yet been accomplished, nevertheless, the assays have generally been shown to have clinical relevance and usefulness.

A comparison of principle and methodological aspects of sperm DNA damage assays

DNA damage assays	Methodology	Principle
Comet assay	Direct	Sperm DNA is subjected to electric field, intact DNA remains in the comet head, whereas DNA fragments migrate to the tail
Sperm chromatin structure assay	Indirect	The acridine orange stain binds to double stranded DNA to emit green fluorescence and to single stranded DNA to emit red fluorescence
TUNEL assay	Direct	Incorporates deoxyuridine triphosphate at the site of single and double strand DNA breaks in a reaction catalyzed by the template-independent enzyme
In situ nick translation	Direct	Incorporates biotinylated deoxyuridine triphosphate at the site of single-stranded DNA breaks in a reaction that is catalyzed by the template-dependent DNA polymerase enzyme
Sperm chromatin dispersion assay	Indirect	Sperm nuclei with increased DNA damage produce very small or no halos, whereas normal sperm is able to release their DNA loops forming large halos
Aniline blue assay	Indirect	The aniline blue stain specifically binds to histones, leaving the protamines unstained
Toluidine blue assay	Indirect	The toluidine blue stain binds to the phosphate residues of sperm chromatin at places where the chromatin is free and not bound to histones or protamines
Chromomycin A ₃ assay	Indirect	The chromomycin A ₃ stain and protamines compete for the same binding sites (guanine–cytosine specific residues), which are present at the minor groove of the sperm chromatin

Introduction

Male infertility is thought to be the root cause or, at least, a contributing factor in 30%–40% of infertile couples. In 1992, the report of a successful pregnancy using intracytoplasmic sperm injection (ICSI) (Palermo et al., 1992) revolutionized the ability to treat male factor infertility and enabled the field to overcome a large proportion of male factor regardless of the specific etiology. These impressive advances have however led to concerns regarding the quality of paternal genome being introduced into the egg when treating these patients. Even when considering the central importance of the paternal genome, sperm is still seen as a minor factor when assessing the infertile couple. Current practice most often comprises a brief medical history and a single semen analysis (SART Committee Report, 2015).

Mammalian sperm cells are, by far, one of the most specialized cells in the human body. Firstly, spermatogenesis entails multiple key cellular functions, including mitosis, meiosis, a complex remodeling of the nuclear chromatin and then a final cellular metamorphosis leading to the stripping of most of the cytoplasm and creation of a tail. Secondly, sperm are designed to accomplish a very difficult mission, involving several consecutive phases, each one independent and highly critical, traversing both the male and female reproductive tracts, burrowing through the egg vestments and completing pronuclear formation. The different components of a spermatozoon each play a crucial role during the conception process (Gagnon, 1999). For example, the head contains DNA/chromatin, which needs to be correctly condensed and decondensed at specific moments; the mid-piece, which contains the energy-generating mitochondria and; lastly, the flagellum transforms energy into movement. In addition, sperm possess all the mechanisms necessary for oocyte recognition and fusion, as well as intracellular structures and factors influencing early embryo development and division (Krawetz, 2005).

DNA/Chromatin Integrity

DNA integrity has been the most studied molecular feature in sperm. Although it is clear that sperm with abnormal DNA/chromatin integrity exist in ejaculates, the clinical utility of this information is controversial.

Sperm DNA fragmentation originates from a multitude of processes, comprising both endo- or exogenous factors and including defective spermatogenesis, abortive apoptosis, protamine defects, ROS attack, different medical pathologies (cancer, varicocele, infections), age, lifestyle influences or working conditions. Sperm has few repairing mechanisms, especially when compared to the demonstrated ability of the oocytes to repair limited damage (Sakkas et al., 2002; Seli and Sakkas, 2005; Sakkas and Alvarez, 2010; Esbert et al., 2011; Meseguer et al., 2011). Several tests are available in order to measure sperm DNA damage, and their application has been discussed extensively (Ribas-Maynou et al., 2013; Schlegel and Paduch, 2005; ASRM Guideline, 2013). This measurable damage may include single or double strand DNA damage or minor chromatin anomalies. The majority of current tests are capable of detecting only gross anomalies and are unable to detect more subtle anomalies. In addition, the lack of standardization among laboratories negatively contributes to the implementation of these techniques on a global scale. These confounders likely influence the results provided by laboratory reports, regarding the effect of DNA damage on sperm function and have resulted in the absence of an accurate and reproducible analysis to predict reproductive success according to DNA damage.

Despite these inconsistencies and concerns, there is a general consensus regarding the link between sperm DNA fragmentation and male infertility. The general fear exists of inadvertently microinjecting a DNA-damaged sperm during ICSI, thereby resulting in worse embryo quality and lower reproductive results, either in pregnancy achievement or on increased miscarriage rates (Bungum, 2012; Collins et al., 2008; Evenson et al., 1999; Fernandez et al., 2000). There have also been studies postulating concerns regarding the child's future health, following implementation of these assisted reproduction techniques (Fernandez-Gonzalez et al., 2008; Ahmadi and Ng, 1999a; Zini and Libman, 2006; Zini et al., 2008). Exactly to which extent DNA fragmentation decreases reproductive results is undetermined and there are conflicting data in the literature as to the utility of the tests (Niederberger, 2011; Payne et al., 2005). However, it seems sufficiently justified that selection of DNA-intact sperm to be utilized in ART will potentially improve results.

Sperm Chromatin Anomalies and Animal Models

Arguably, the most critical component in relation to successful in vitro fertilization or intracytoplasmic sperm injection is the sperm nucleus. In animal studies the relationship between an abnormal sperm nucleus, in particular the DNA or chromatin packaging, has been shown to have negative effects on reproductive outcome and progeny (Hales et al., 1992; Robaire and Hales, 2003; Anway et al., 2005). Some of the most intriguing studies have shown that, when sperm are exposed to gamma radiation prior to insemination, the proportion of nuclear DNA-strand breaks increased when sperm were subjected to between 5 and 100 GY. Interestingly, when the irradiated sperm are used to fertilize, live birth rate decreased dramatically, from over 50% in controls to 0%–20% when sperm were exposed to high doses of radiation (Ahmadi and Ng, 1997, 1999b). In other studies, disruption of

the paternal nuclear DNA has even led to transgenerational effects on offspring, in particular when endocrine disruptors are investigated (Skinner, 2016).

Sperm Chromatin Testing in the Human

With the known impact of sperm nuclear DNA in animal studies, it was subsequently postulated that testing the chromatin of human sperm would assist in the diagnosis and treatment of male factor infertility. Over 30 years ago, Evenson et al. (1980) demonstrated a relationship between mammalian sperm chromatin heterogeneity and fertility in human. The same group went on to perform the Georgetown Study (Evenson et al., 1999), which correlated sperm DNA integrity with pregnancy outcome. They described an analysis which they termed the Sperm Chromatin Structure Assay (SCSA). They provided SCSA values of human semen samples from 165 presumably fertile couples wishing to achieve pregnancy over 12 menstrual cycles. SCSA data from the male partners of 73 couples (group 1) achieving pregnancy during months 1–3 were compatible with “high fertility.” These SCSA values were significantly different from both couples (group 3) achieving pregnancy in months 4–12 or those who failed to achieve pregnancy ($P < .001$). Of the numerous sperm DNA integrity tests now available, the SCSA has become the most utilized test of sperm chromatin. The tests that are most commonly used to assess the sperm nucleus are described in the following paragraphs.

SCSA (Sperm Chromatin Structure Assay)

In this technique, the presence of DNA fragmentation is indirectly evaluated by examining the susceptibility of the sperm DNA to acid denaturation in situ, followed by staining with acridine orange (Evenson, 1990). By using flow cytometry, around 5000–10,000 sperm can be assessed in a few seconds. The percentage of red sperm (DNA fragmentation index or DFI) represent those sperm with denatured DNA, which in a normal semen sample should be under 27%–30% (Evenson et al., 1980; Virro et al., 2004). Specific SCSA-software can then determine the ratio between normal and abnormal sperm.

TUNEL (Terminal Deoxynucleotidyl Transferase dUTP Nick End Labeling)

This technique allows the evaluation of single or double stranded DNA damage. It measures the presence of 3′OH free groups, which are products of broken DNA strands. It is based on the fact that the enzyme “deoxynucleotidyl transferase” (TdT) allows for labeling of the DNA nicks through deoxyuridine triphosphate (dUTP). Similar to the SCSA, a fluorescent signal bound to the enzyme is then used to quantitate thousands of sperm using flow cytometry.

Comet Assay

This technique utilizes electrophoresis, and the principle that the fragmented DNA has a greater migrating velocity toward the anode of the electrophoretic field compared to that of intact DNA. This assay can be done at a neutral or alkaline pH, but may lead to an overestimation of broken DNA in the sperm (Shamsi et al., 2010). The reference ranges reported in the literature vary widely among authors (Tamburrino et al., 2012), as there is no standardized protocol.

SCD (Sperm Chromatin Dispersion or Halo Test)

The SCD or Halo technique identifies a differential in decondensation of the chromatin between those sperm with fragmented DNA and intact DNA. This is achieved by using an acid treatment followed by deproteinization, so that those sperm with fragmented DNA would not release DNA loops and do not generate a chromatin dispersion halo. Those sperm without DNA fragmentation demonstrate a big halo that corresponds to the DNA loops. It has been reported that, using this technique, the chances of achieving a pregnancy is very low if at least 30% fragmentation is identified (Fernandez et al., 2005).

Clinical Validation

The validity of these various sperm chromatin tests and their reliable prediction of reproductive outcome has been controversial over the years. Initial studies related the tests to both natural fertility and the use of intrauterine insemination. Indeed, the Georgetown Study (Evenson et al., 1999) mentioned above, and subsequent studies on IUI provided good evidence as to the validity of sperm chromatin testing. Bungum et al. (2004), in particular, demonstrated that when IUI was performed the chance of pregnancy/delivery was significantly higher in the group with $DFI \leq 27\%$ than in patients with $DFI > 27\%$. The odds ratios (ORs) (95% confidence intervals) were 20 (2.3–117), 16 (1.9–137), and 14 (1.6–110) for biochemical pregnancy, clinical pregnancy, and delivery, respectively.

In the IVF setting, sperm DNA fragmentation has been associated with reduced fertilization rates (Liu and Baker, 1992), embryo quality (Seli et al., 2004), pregnancy rates (Evenson et al., 1999) and increased miscarriage rates (Carrell et al., 2003). The various methods used to test sperm DNA fragmentation such as the SCSA, the sperm chromatin dispersion (SCD) test, the TUNEL assay and

the Comet assay were recently compared in a systematic review and meta-analysis to assess their value of measuring sperm DNA fragmentation and predicting the chance of ongoing pregnancy with IVF or ICSI.

The recent study by Cissen et al. (2016) examined 658 unique studies, however only 30 met the inclusion criteria for the metaanalysis. They reported that, overall, sperm DNA fragmentation tests had a reasonable to good sensitivity. When they constructed a hierarchical summary receiver operating characteristic (HSROC) curve they only found that the TUNEL assay (area under the curve (AUC) of 0.71; 95% CI 0.66–0.74) and Comet assay (AUC of 0.73; 95% CI 0.19–0.97) had a fair predictive capability for the chance of pregnancy. In their analysis, the SCSA and the SCD test had poor predictive capacity. They concluded that, at present, the current sperm DNA fragmentation tests have limited capacity to predict the chance of pregnancy in the context of IVF and ICSI.

One area of increasing clinical interest, in relation to the sperm chromatin anomalies, is the data demonstrating that high levels of DNA fragmentation are associated with recurrent pregnancy loss (Carrell et al., 2003; Ruixue et al., 2013; Ribas-Maynou et al., 2012). It is possible that while DNA compromised sperm may be able to reach and fertilize the eggs, there may be subsequent detrimental effects on the development of the embryo and fetus.

The question has arisen regarding the difference in predictive capability of sperm fragmentation tests between IUI and IVF? One of the main reasons is that the sperm utilized for IVF or ICSI is prepared in a different manner. It could be argued that the preparation of sperm for IVF or ICSI removes many of the abnormal sperm which could contribute to higher sperm DNA fragmentation levels. For example, in our own studies (Tomlinson et al., 2001) we showed that density gradient centrifugation enriched samples by improving the sperm nuclear integrity (by 450%), when comparing the fresh semen sample to the postpreparation samples ($N = 140$: 9% in semen versus 2% postpreparation). In addition, selection of even grossly motile normal sperm by an embryologist performing ICSI may add another layer of sperm selection that would eliminate sperm with abnormal DNA integrity.

New Tests of DNA Integrity

A number of new methodologies are now being developed to provide a different perspective on sperm DNA integrity. One of these is based on genome-wide sperm deoxyribonucleic acid (DNA) methylation patterns. In a recent study by Aston et al. (2015) they evaluated whether male fertility status and/or embryo quality during in vitro fertilization (IVF) therapy can be predicted by the DNA methylation status of sperm. They examined normospermic IVF patients who were separated into two groups: patients who had generally good embryogenesis and a positive pregnancy ($n = 55$) and patients with generally poor embryogenesis ($n = 72$; 42 positive and 30 negative pregnancies) after IVF. Their analysis revealed that sperm DNA methylation patterns differed significantly and consistently between the two groups. They concluded that DNA methylation patterns may be predictive of embryo quality during IVF.

Conclusion

Although the correlation between sperm chromatin/DNA integrity and reproductive outcome is less clear in the human than in animals, the current data on human sperm DNA testing suggests the following:

- (i) the presence of DNA damage in a high proportion of spermatozoa from a raw semen sample, is associated with a decreased likelihood of fathering a child, regardless of semen analysis parameters (Bungum et al., 2004);
- (ii) While a specific threshold or percentage of DNA-damaged sperm that is incompatible with pregnancy has not been established, it may be used during the initial evaluation of the infertile couple to guide management regarding which couples should undergo fewer IUI cycles in favor of early IVF/ICSI (Bungum et al., 2004);
- (iii) current sperm-DNA integrity tests are better at predicting reduced success with natural and IUI attempts at pregnancy than attempts using IVF or ICSI (Bungum et al., 2004, 2008; Zini et al., 2008).

Although the clinical application of the numerous sperm DNA integrity tests is still controversial (Collins et al., 2008), it is undeniable that infertile men or men from infertile couples have a higher frequency of abnormal results from DNA integrity testing than fertile controls (Tomlinson et al., 2001). It is also becoming more apparent that removal of DNA damaged sperm from the IVF or ICSI prepared samples can improve outcomes for patients (Worrlow et al., 2013). There is also mounting evidence that sperm DNA integrity abnormalities in men are associated with higher miscarriage rates (Carrell et al., 2003; Ribas-Maynou et al., 2012; Ruixue et al., 2013).

The reason why ejaculated sperm possess chromatin and DNA anomalies still remains unclear. The possible mechanisms hypothesized include: apoptosis in the seminiferous tubule epithelium; defects in chromatin remodeling during the process of spermiogenesis; oxygen radical-induced DNA damage during sperm migration to and while in the epididymis; the activation of sperm caspases and endonucleases; damage induced by chemotherapy and radiotherapy; and the effect of environmental toxicants (Sakkas and Alvarez, 2010; Aitken and Curry, 2011).

IVF reproductive technologies have come a long way since the birth of the first baby born, utilizing IVF technology, in 1978. The technical progression from routine insemination to ICSI for treating many male infertility patients has changed the way we prepare sperm. It is now coming to light that the role of the paternal genome in influencing the success of IVF is more than once thought. We

now recognize that more importance should be placed on sperm preparation techniques and many research laboratories are now striving toward the development of novel techniques for sperm preparation and selection.

Introduction

The mammalian sperm contains a very specialized and singular epigenetic landscape that is essential for biology and fertility. DNA methylation, spermatozoal RNAs and nuclear protein composition are marks thought to be remnants of epigenetic transitions occurring during spermatogenesis even though some of them can influence fertilization and embryogenesis (Hammoud et al., 2009). The main difference between sperm and somatic cells is the replacement of 90%–95% of histone proteins with protamines, thus allowing a tighter DNA compaction with the formation of toroid structures necessary for sperm motility and protection of DNA from oxidation and fragmentation (Jenkins and Carrell, 2011; Oliva, 2006).

Epigenetics in normal cell function is well described and has been implicated in many diseases. Yet, its use in the field of fertility is only beginning to be explored even though it is still not well understood. The use of epigenetic signatures as potential markers for diseases related to fertility or as predictors in assisted reproductive techniques (ART) is currently being investigated. Because of the unique nature of the sperm epigenome and how the patterns found in mature sperm can possibly perturb spermatogenesis, some researchers believe that these marks could provide predictive insight on infertility and pregnancy outcomes.

Several techniques have been developed to study these different epigenetic marks (Table 1). Each of them can yield tremendous amounts of data about the patterns associated with different forms of fertility phenotypes. Furthermore, these techniques could potentially be useful as diagnostic tools in the foreseeable future and provide so much more data than the current tests used clinically to diagnose male fertility.

Table 1 Experimental approaches for profiling genome-wide epigenetic marks in sperm

Technique	Analysis	Advantages	Disadvantages
CHARM	Methylation	• Analysis of CpG sites genome-wide regardless of proximity to genes or CpG islands	• Moderate resolution • Limited regions near enzymes recognition sites
Affinity enrichment-based methods	Methylation	• Detection of DMRs within high or low CpG density regions • Can discriminate 5mC from 5hmC • No mutation introduced • More sensitive than MeDIP in regions with higher CpG density	• Low resolution • Biased toward hypermethylated regions
MeDIP	Methylation	• No mutation introduced • Specific to 5mC/5hmC depending on the antibody • More sensitive in regions with low CpG density	• Biased toward hypermethylated regions • No identification of single 5mC sites • No prediction of absolute methylation level
Bisulfite conversion-based methods	Methylation	• Evaluate methylation state of almost every CpG sites	• High cost • Bisulfite treatment can degrade DNA • No discrimination between 5mC and 5hmC
Single-cell methylome	Methylation	• Highly sensitive • Detect target CpG sites at high coverage with low number of sequence reads	• Bisulfite treatment can degrade DNA • No discrimination between 5mC and 5hmC • Poor coverage for imprinting loci
Pyrosequencing analysis ChIP	Methylation Histones	• Measurements of individual CpG dinucleotides • Very efficient immunoprecipitation	• Not a genome-wide approach • Not applicable to non-histone proteins • Risk of protein rearrangement during chromatin preparation and precipitation • May have selective digestion of particular chromatin domains during preparation
RNA extraction	ncRNAs	• Pure preparations of RNA	• Depending on the method used, small RNAs cannot be recovered

DNA Methylation

DNA methylation is one of the most studied epigenetic modifications. A methyl group will be added on the fifth carbon of cytosine (C) forming 5-methylcytosine (5mC) by catalysis of DNA methyltransferases (Dnmts) (Smith and Meissner, 2013). DNA methylation occurs mainly in CpG dinucleotides (CpGs) even though it can also be found, less frequently, in non-CpG context (Kim et al., 2014). DNA methylation has been associated with a large number of cellular processes such as X chromosome inactivation, embryonic development, genomic imprinting, transcriptional repression, alteration of chromatin structure, and transposon inactivation (Wilson et al., 2012). These methyl marks are heritable but more interestingly certain methylation patterns have transgenerational effects (Li et al., 2015b). DNA methylation is very different depending on the organism studied. In human embryonic stem cells for instance, DNA methylation occurs in up to 80% of CpGs with the remaining unmethylated CpG residues enriched in CpG islands (CGI) located at gene promoters (Chen et al., 2011). On the contrary, in invertebrates like *Drosophila*, methylation levels are extremely low (Lyko et al., 2000).

These important findings on DNA methylation would not have been possible without the development and advancement of experimental and computational profiling approaches.

Sperm DNA Extraction

Classic high quality DNA extractions developed for mammalian somatic cells are ineffective for sperm. In fact, unlike somatic cells, sperm DNA is highly compacted by the replacement of histones with sperm-specific proteins called protamines. These protamines and the disulfide bridges formed within and between protamines inhibit the extraction of sperm DNA by standard techniques (Griffin, 2013).

A wide variety of methods have been developed to extract DNA. In 1988, Bahnak et al. described a guanidinium protocol for the isolation of mammalian spermatozoa (Bahnak et al., 1988). This protocol was later modified by Hossain et al. replacing the lengthy ultracentrifugation steps with the use of isopropanol and proteinase K for digestion (Hossain et al., 1997). Commercial companies have also based their kits on this guanidine thiocyanate method for the isolation of RNA, DNA, and protein. But, these kits utilize toxic chemicals such as chloroform and phenol. This was counterbalanced by the development of column purification of the DNA following lysis.

In round spermatids, somatic histones are replaced by testis-specific transition proteins during spermiogenesis. To have a highly condensed chromatin, transition proteins are later replaced by protamines in the elongated spermatid which will then be phosphorylated (Brewer et al., 2002; Dadoune, 1995). Once the protamines bind to the DNA, most of the phosphate groups are removed and

cysteine residues become oxidized and form disulfide bridges that link the protamines together. During sperm DNA extraction, a supplemental dissociation of nucleoproteins from nucleic acids is required. Dithiothreitol (DTT) and 2-mercaptoethanol enable to cleave disulfide bonds and allow proteins to unfold completely. DTT is known to be more effective, less toxic, quicker and the odor is more tolerated than 2-mercaptoethanol. Sodium dodecyl sulfate (SDS) is routinely used in DNA extraction methods. Sodium lauroyl sarcosinate (Sarkosyl), like SDS is also used to denature proteins and disrupt biological membranes. However, Sarkosyl, on the opposite of SDS, has an excellent solubility in chaotropic solutions. Extraction buffers used contain EDTA which removes metal ions potentially present in the seminal fluid, or on the cell surface and will thus reduce contamination in the final DNA extract. The addition of isopropanol facilitates DNA precipitation. An incubation at room temperature with sodium citrate and alcohol will concentrate any remaining chaotropic salts into the solution while the DNA will stay precipitated. In fact, sodium ions in the presence of alcohol neutralize the negatively charged phosphate groups on the DNA backbone facilitating its precipitation.

The first studies on DNA methylation determined the methylation status of genes of interest and quantified the total amount of 5mC. Thanks to microarray hybridization technology, studies on DNA methylation were able to scale up to the genome-wide-level. Nowadays, next-generation sequencing platforms are able to construct genomic maps of DNA methylation at single-base resolution. Enzyme digestion, affinity enrichment and bisulfite conversion are currently used for that purpose. The most recent development in the epigenomic profiling is a single-cell methylome, and the use of third-generation sequencing in detecting DNA methylation in real time.

Restriction Enzyme-Based Methods

These techniques use methylation-sensitive restriction enzymes (MREs) such as *BstUI*, *HpaII*, *NotI*, and *SmaI* which cleave only unmethylated target sequences leaving then the methylated DNA intact. This MRE digestion coupled with sequencing technologies can predict genome-wide DNA methylation levels (Maunakea et al., 2010). During the sequencing step, the DNA fragments from this cleavage are size-selected and sequenced. The results reveal the locations of the unmethylated CpG sites within the recognition sites of the enzyme utilized (Li et al., 2015a).

In conclusion, MRE-Seq estimates the relative DNA methylation levels with a low coverage of the genome.

Comprehensive High-Throughput Arrays for Relative Methylation (CHARM)

This method uses the enzyme McrBC digesting methylated DNA to fractionate it. McrBC cleaves half of the methylated DNA and all the methylated CpG islands (CGI). This enables to relatively size-select unmethylated DNA and subsequently utilizes hybridization arrays. Thus, CHARM is able to detect differentially methylated regions (DMRs) at CGI shores (sequences up to 2 kb away from CGI) which are not detectable with methods such as methylated DNA immunoprecipitation (MeDIP).

Affinity Enrichment-Based Methods

As the MeDIP, these affinity enrichment-based methods use antibodies specific for 5mC or methyl-CpG-binding domain (MBD) proteins to enrich methylated DNA regions. This MBD protein-based approach relies on the capacity of MBD proteins to bind specifically to methylated DNA sequences followed by a microarray (MBD-chip) or sequencing (MBDCap-seq/MethylCap-seq) (Brinkman et al., 2010), methylated DNA capture by affinity purification technologies.

Methylated DNA Immunoprecipitation (MeDIPs)

Using an anti-methylcytosine antibody, MeDIP is able to immunoprecipitate DNA with methylated CpG sites. These DNA fractions enriched by MeDIP can be evaluated using tiling arrays (MeDIP-chip) or high-throughput sequencing (MeDIP-seq). This technique usually yields a resolution of 100–300 bp. MeDIP-seq generates the relative enrichment of methylated DNA across the genome instead of predicting the absolute DNA methylation level. Because of the low amount of DNA needed (as low as 1 ng), this method can be used to profile DNA methylation in minute DNA samples, rare cell types and microdissected tissues (Taiwo et al., 2012; Zhao et al., 2014). However, in MeDIP, CpG-rich fragments are more likely to be enriched than CpG-poor ones even if they are fully methylated, a computational correction to normalize CpG content across a wide range of CpG densities is always required (Down et al., 2008).

Bisulfite Conversion-Based Methods

This technique is based on the deamination of unmethylated C to uracil (U) residues on the genomic DNA, whereas methylated C residues remain unaffected. The U eventually converts to thymine (T) in a subsequent polymerase chain reaction (PCR). The methods based on this bisulfite conversion provide single-base resolution. When investigating specific DNA sequences or studying genome-wide methylation via a methylation array, whole-genome bisulfite sequencing and reduced-representation bisulfite sequencing are commonly used.

Single-Cell Methylome

Generally, most genome-wide DNA methylation profiling techniques need bulk cell populations as starting materials. It is also impossible to assess the methylation heterogeneity among individual cells. To overcome this issue, single-cell bisulfite-based techniques have been developed. To reduce DNA loss and provide information on approximately 1 million CpG sites within an individual mouse or human cell, steps of *MspI* digestion have been integrated to the bisulfite conversion. These techniques are ideal in studies with limited cell amounts and heterogeneous cell populations. They are especially practical for sperm cells, oocytes, primordial germ cells, and embryonic stem cells (Guo et al., 2015; Schwartzman and Tanay, 2015).

Pyrosequencing Analysis

Pyrosequencing provides an analysis of the methylation pattern at a specific site of 25–50 bp. It allows measurement of the methylation percentage of individual CpG dinucleotides, a certain flexibility in sequencing primer position to analyze any CpG sites. This technique is only used for specific sites and it is not possible to use it as a genome-wide approach as many regions of the genome cannot be analyzed with this protocol.

Third-Generation Sequencing

The epigenetics field is evolving rapidly and with it the technologies associated. Emerging third-generation sequencing such as single-molecule real-time sequencing or nanopore sequencing are perfect examples. The first technique enables to detect directly modifications by monitoring the activity of DNA polymerase during the incorporation of different nucleotides labeled with fluorescence into complementary DNA strands. In the second technique, single-strands of DNA are pulled by a phage DNA polymerase through a bacterial pore in single-nucleotide steps and the ion current through the pore is recorded (Laszlo et al., 2013).

All together, these third-generation sequencing techniques will allow researchers to make more discoveries on the different epigenetic modifications and could reveal novel functions of these epigenetic marks in gene expression. However, before their application is extended, the throughput and accuracy must be substantially improved before applying them to studies involving complex genomes (Yong et al., 2016).

Histone Modifications

Histones order DNA into structural units called nucleosomes. They are the major protein component of chromatin and are subject to several different post-translational modifications, including methylation, acetylation, phosphorylation, ubiquitylation, and sumoylation.

The positive charge of the lysine residue on histone tails usually leads to a tight association with negatively charged DNA. Histone acetyltransferases (HATs) are enzymes initiating the formation of euchromatin from heterochromatin. HATs catalyze the transfer of an acetyl group (CH_3CO) to a conserved lysine on the histone tail. Acetylation of histones typically leads to relaxed chromatin and is associated with activation of transcription. In contrast, histone deacetylases (HDACs) catalyze the removal of acetyl groups from histones, consequently leading to more tightly packaged chromatin. The recruitment of HATs and HDACs is tightly regulated by DNA binding proteins located near epigenetic target regions. The methylation of specific amino acids on histones can lead to the formation of heterochromatin with consequent repression of transcription.

The interaction between histones and DNA is most often studied using a technique known as chromatin immunoprecipitation (ChIP). This method requires the use of highly specific antibodies directed against DNA-binding proteins and can be followed by a number of nucleic acid analysis techniques, such as PCR, qPCR, sequencing, and microarray hybridization. ChIP determines whether certain histones are associated with specific genomic regions and also identifies regions of the genome associated with specific histone modifications—methylation and acetylation being the most studied ones.

Chromatin Immunoprecipitation (ChIP)

To map histone modifications, chromatin is normally isolated under either fixed or native conditions. Sperm is treated with a reducing agent in order to reduce and prevent intramolecular and intermolecular disulfide bonds from forming between cysteine residues. The sperm is subsequently resuspended in a lysis buffer containing some detergents, whose concentrations are crucial to an efficient chromatin shearing. This shearing can be proceeded by an enzymatic digestion (usually a micrococcal nuclease) or by a sonication method. The genomic DNA that is not protected by histones will be divided in fragments around 150–250 bp (150 bp being the size of one nucleosome). After that histones will be detected in the soluble chromatin fraction while protamines are spun down. This chromatin can be directly used in ChIP to map histone variants, modifications or retention in sperm. To do the immunoprecipitation, an incubation with an antibody against histones or histone modifications is used. Then the antibody–chromatin complexes will be captured using beads and the bound chromatin is eluted. The immunoprecipitated DNA is obtained by a phenol/chloroform extraction. The DNA associated with histones and histone modifications can be characterized by candidate specific quantitative PCR (qPCR) approaches or genome-wide high-throughput sequencing. However, even if qPCR is a valid

technique, because the isolated DNA is around 150 bp in size, designing one or both primers outside these small fragments can lead to mistaken conclusions (Hisano et al., 2013).

Non-Coding RNA

A very large number of transcripts do not appear to encode for proteins. These transcript species are known as noncoding RNAs (ncRNAs). For a long time, they have been considered as “junk” in the genome, but emerging evidence has highlighted that ncRNAs can have a wide variety of functions. Complex eukaryotes such as fungi, plants, and animals have >50%, a number rising to ~98.5% noncoding DNA in humans (Amaral et al., 2008). Non-coding RNAs can be classified according to length: the small ncRNAs (sncRNA) with a length <200bp; anything longer than that is referred to as long ncRNA (lncRNA). Examples of short ncRNAs include rRNA, microRNA (miRNA), siRNA, and Piwi-interacting RNA (piRNA). Both of these ncRNAs have been shown to be implicated in spermatogenesis (Bettegowda and Wilkinson, 2010; Chuma and Nakano, 2012; Lee et al., 2012; Yadav and Kotaja, 2014).

Small non-coding RNAs are generally identified by RT-PCR analysis, in situ hybridization, or small RNA sequencing studies. Besides, the recent development of microarray technologies has permitted the global analysis of spermatozoal microRNAs (miRNAs) allowing different research teams to determine different expression profiles between fertile and infertile men (Hamatani, 2011; Kotaja, 2014). Large non-coding RNAs are also predominant in sperm and can be analyzed in a sequencing analysis.

The sperm contains reduced cytoplasm, low amounts of full-length RNAs along with biologically degraded RNAs, and highly protamine-condensed DNA. Due to this complex nature, the isolation of RNA from sperm is unique compared to somatic cells.

To isolate total RNA, the sperm membrane and nucleoprotamine complex have to be completely dissolved. Variations of two methods have historically been used to prepare RNA from natural sources (e.g., tissue samples, whole organisms, cell cultures, bodily fluids): chemical extraction and immobilization on glass, often referred to as solid-phase extraction. Chemical extraction methods typically use highly concentrated chaotropic salts in conjunction with acidic phenol or phenol-chloroform solutions to inactivate RNases and purify RNA from other biomolecules. These methods provide very pure preparations of RNA. But, the RNA must typically be desalted and concentrated with an alcohol precipitation step. This alcohol precipitation does not quantitatively recover small nucleic acid molecules, making it ill-suited for the preparation of very small RNAs.

The second method, solid-phase extraction, is based on high salt or salt and alcohol to decrease the affinity of RNA for water and increase its affinity for the solid support used. However, this solid-phase purification of RNA does not effectively recover small RNAs.

Some companies have developed isolation procedures combining the advantages of organic extraction and solid-phase extraction while managing to recover small RNAs. The use of ethanol immobilizes the large RNAs through a glass-fiber filter and the small RNAs are collected in the filtrate. For non-coding RNAs (ncRNAs), an enrichment is usually necessary. Candidate-specific RT-PCR, microarrays or genome-wide high throughput sequencing analysis can be used to characterize the nature of these ncRNA.

Epigenetic Human Sperm Analysis

Clinical Potential Use

Epigenetics has been well studied in normal cell function and has also been implicated in many diseases (Momparker, 2003). Its use in fertility is however just starting to be explored. The multiple factors involved in epigenetics such as the variables involved, the poor description of normality as each cell type has unique signatures with some degree of variation and the type of epigenetic mark being assessed; make it challenging and hard to understand. With our current understanding of the epigenome, we cannot predict the potential biological impact of a change in DNA methylation (Jenkins et al., 2017). The emergence of extremely high resolution techniques enabling for instance a single cell resolution of complete transcriptomes, provides remarkable insight into epigenetics at the single cell resolution which can offer tremendous possibilities in both research and diagnostic development. Despite these limitations, many epigenetic signatures in sperm have been tightly associated with a number of sperm abnormalities and/or clinical outcomes such as protamine levels in sperm from fertile and infertile human males (Jenkins and Carrell, 2011). Using epigenetic signatures as potential markers for various fertility related diseases and/or as predictors for success in ART is becoming more widely explored (Aston et al., 2015; Jenkins et al., 2016; Jodar et al., 2015). The high resolution techniques enable to screen large portions of the epigenome and create a huge amount of data available which can help understand the relationship between the sperm epigenome and various fertility phenotypes (Hrdlickova et al., 2017). 684 RNA “elements” have been identified as being required to facilitate the best chances at successful IVF outcomes and the absence of even one of these elements has been shown to decrease the success rate in various fertility treatments (Jodar et al., 2015). Another study identified genetic markers which could be useful as a complement for classical semen analysis in order to identify sperm donors with less favorable in utero insemination reproductive outcome despite having normal semen parameters (Bonache et al., 2012). DNA methylation techniques have progressed greatly these last years and they are commonly used in the assessment of sperm DNA methylation patterns. For instance, Aston et al. identified in the mature sperm some methylation patterns which could predict the likelihood for a man to go through IVF or if a less invasive procedure might be effective (Aston et al., 2015).

It is well known that the current available diagnostic tools to establish a man's reproductive potential are lacking (WHO, 2010). Many researchers have highlighted the need to innovate and improve approaches with better predictive power for male infertility diagnosis purpose. Assessing the DNA methylation seems to be the easiest option as it remains remarkably stable throughout spermatogenesis (Hammoud et al., 2014) whereas RNA transcripts and histone retention/modifications change dramatically. Yet, discriminating one epigenetic mark rather than another is less likely to offer a better understanding in the etiologies of commonly seen sperm disorders. These techniques, even though not presently applicable clinically, will probably help develop predictive tools to assess an individual's ability to procreate.

Raman Microspectroscopy

Grace M Centola, Reproductive Laboratory and Tissue Bank Consultant, Port St Lucie, FL, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Standard assisted reproductive procedures allow an individual sperm to be injected into the egg. A sperm is chosen from a cell culture dish under a microscope by a technician based on the light microscopic appearance of the sperm. However, there has been no method to determine the internal structure of the cell nucleus and organelles, which may be abnormal or not functional even when the microscopic appearance of the sperm cell is normal. Sperm DNA damage is being rigorously studied, since this type of damage could be the cause of poor embryo quality, poor implantation, and poor development (Speyer et al., 2010; Mallidis et al., 2011).

Current microscopic methods are limited because they require that cells are fixed, stained with a toxic dye, and/or embedded in plastic and cut into thin pieces to examine under a microscope. Thus, damaged cells would not be able to be used clinically, and in the case of sperm, could not be used for assisted reproduction (Mallidis et al., 2011).

Raman microspectroscopy is a laser scattering technique that uses vibrational, rotational, and low-frequency laser scattering to detect the fingerprint of a cell's chemical composition (Mallidis et al., 2014). RMS detects the internal structure of molecules which comprise the "fingerprint" of a cell (Mallidis et al., 2011). For RMS, cells are air dried onto a glass slide and then examined using a special laser with filters and light scattering detectors. The spectral map at selected wavelengths is then imaged based on the area within the cell. Although the cells are dried onto the slide, current research focuses on refining the technique to allow the cells to remain functional after analysis (Mallidis et al., 2013; Liu et al., 2013; Ma et al., 2013).

Raman spectroscopy, combined with three-dimensional spatial resolution of confocal microscopy, can detect changes in specific molecules in the cell and thus assist in diagnosis and characterization of pathology (Mallidis et al., 2011, 2014). Normal and abnormal cells and organelles demonstrate a unique RMS spectrum. Thus RMS has been shown to detect oxidative damage to the nuclear DNA of individual human sperm (Sanchez et al., 2012; Sigman, 2012). Furthermore, Raman microspectroscopy has been used to distinguish sperm bound to the egg (i.e., functional) as compared to unbound sperm (Liu et al., 2013). Additionally, RMS has been shown to detect complete and incomplete sperm production in testicular tissue from men presenting with no sperm in the ejaculate (Ma et al., 2013; Liu et al., 2014).

Raman microspectroscopy is an accurate and reproducible procedure for the assessment of sperm DNA structure and the sites of nuclear DNA damage. It holds promise for resolving the issue of idiopathic male infertility and ultimately can assist in the selection of a "normal" sperm for use in assisted reproductive procedures.

IVF LABORATORY

Setting Up the IVF Laboratory

Jason E Swain, CCRM IVF Network, Lone Tree, CO, United States

Charles L Bormann, Massachusetts General Hospital, Boston, MA, United States

© 2018 Elsevier Inc. All rights reserved.

Background

It is a daunting endeavor to design and equip a new IVF laboratory. Numerous factors must be considered, including space requirements and layout to accommodate laboratory staff, equipment and workflow. Proximity to other associated rooms, like collection rooms, laboratory supply storage, medical gas storage, operating/procedure rooms and transfer rooms, as well as gamete and cryostorage areas are also relevant factors.

Initial planning for estimated volumes, as well as the ability to expand in the future is desirable. Each facility will also have to consider unique requirements as space planning takes place, factoring for areas like hormone analysis, andrology, fertility preservation, third party reproduction, genetic counseling, etc. The range of patient services offered at the clinic impacts the ultimate size and layout of the space.

Although daunting, commonalities do exist between highly successful programs in terms of how the IVF laboratory is constructed and equipped. During construction, extra care should be taken to provide an environment with proper air quality, low in volatile organic compounds (VOCs). This is accomplished via selection of appropriate construction materials as well as a proper HVAC system to provide desired air quality. In addition, key “burn-in” steps are often taken prior to clinical use to ensure proper functioning of the space.

In this article we will discuss the common elements to establish and equip a modern IVF laboratory, including: workflow and space planning, HVAC and medical gases, construction management, construction materials and equipment, safety, security and risk management, and lastly, burn-in. Of paramount importance is constant oversight during the construction process to ensure key details are met. Once these requirements have been met, diligence and a thorough quality management program are required to ensure that optimal laboratory conditions remain intact.

Space and Workflow Planning

One of the first steps in undertaking the building of a new IVF laboratory includes compiling a list of core functions necessary for the space and then subsequently mapping the layout of the required areas, taking care to note requirement for proximity relative to each other and the ancillary functions of the clinic. The core functions within the IVF laboratory (media preparation, sperm processing, egg retrieval, cumulus cell removal, micromanipulation, embryo culture, and cryopreservation), should be mapped relative to each other to layout the space within the laboratory. Care should be taken to consider distance between key procedural areas and traffic flow to avoid areas of congestion and also improve efficiency. Within the laboratory, this includes avoiding areas where workflow/employee movement may cross and create a potentially hazardous encounter.

For ancillary functions related to the lab, such as patient reception/waiting, specimen collection rooms, operating room/retrieval rooms, embryo transfer rooms, lab storage, and medical gas storage; consideration should be given to proximity to the laboratory to improve the patient experience and consider efficiency of laboratory workflow.

Each functional area should be adequately supplied with essential services, such as plumbing, electrical/emergency power, appropriate gas lines, HVAC, lighting, emergency alarm system, and IT network architecture as needed.

Once key areas of need are identified and workflows mapped, consideration of space requirements can be adjusted based on patient volumes and number of staff. Within the laboratory, this includes number of hoods, incubators, microscopes, micromanipulators, lab supply storage, and computers; as well as sufficient office/desk space.

Additional considerations for space planning may include designating a space for training new laboratory staff or for research. This space may include a fully functional workstation, incubator, and micromanipulation setup which would allow staff to practice new skills without disrupting clinical workflow or inadvertently changing the settings of clinical lab equipment.

Construction

As part of the design and construction process, specific requirements should be provided to the architect and construction management teams.

Construction Materials

Low or no VOC materials must be used in IVF laboratory construction. This includes all flooring, paint, adhesives, insulation, counter tops, and furniture.

Insulation: Care to use proper insulation is needed, as chemicals like formaldehyde are often present. Presence of insulation on the direct periphery of the IVF lab should be avoided if possible. If unable due to presence of an outside wall, a formaldehyde-free product should be used. Another option includes use of mineral wool. Of note, insulation may be useful for use around rooms that may require sound dampening, such as collection rooms or offices near key patient areas.

Flooring: Welded instead of glued seams of sheet vinyl flooring are recommended for sanitary reasons as well as minimal VOC release. A low VOC adhesive is required when laying lab flooring, as well as flooring in surrounding areas.

Paints: Latex based non-VOC paints should be used on all painted surfaces in and around the IVF laboratory.

Cabinetry: Powder coated metal cabinetry or stainless steel is recommended to avoid concerns with laminate and particle board, which would likely contain adhesives with high levels of VOCs.

Doors: Solid metal doors are often recommended. Door closers are useful on certain doors, as well as door stops. Consideration should be given to function to determine which hardware is required. Some doors may require security (keyed locks, coded locks, or electronic locks) or automatic door openers. Some doors may benefit from windows to avoid collisions as staff enter and leave the lab.

Furniture: purchase all medical or lab grade chairs with vinyl coated seating surfaces easily cleaned from any contamination. Tables and countertop should be made of either Epoxy or Corian or some other hard material devoid of adhesives (avoid laminate).

HVAC

The heating and air conditioning system must be considered when designing a modern IVF laboratory. This critical aspect will control temperature, humidity, and air quality. It is helpful to decide early on whether a commercially available “plug-and-play” filtration system will be used or if the contractors will build a custom unit. Regardless of the choice, the system should be dedicated to the IVF laboratory, and achieve positive pressure in the lab. It is often recommended that Tyvek wrapping, a hard deck ceiling, gasketed lights and doors, and door sweeps are included to achieve full insulation of potential air seepage to obtain positive pressure. Air exchanges should be considered to maintain positive pressure, but also filtration to achieve the desired air quality. Filtration should include prefilters (MERV) and HEPA filtration to remove particulates. Importantly, filtration should also reduce VOC content and may include the use of UV light for photocatalytic oxidation or use of chemical filter beds with carbon and potassium permanganate mixtures. The placement of the filtration system is important and should be as close to the outlet air ducts in the lab as possible to avoid the risk of introducing contaminants in-line after the filters. Only metal ductwork that has been precleaned should be used. Ductwork should remain sealed during the construction process to avoid contamination. Ensure that a proper water supply is drawn to the HVAC unit to allow for humidity control. A special consideration for the IVF lab, which may not be present in other types of medical laboratories, is proper placement of air supply ducts that ensures they are not directly above/near ICSI stations or incubators, as this will impact temperature regulation of the stage warming units. Assessment of air quality after install and before clinical cases commence is recommended to ensure expected standards are met. This can be achieved through contracting with an air quality expert or via commercially available air quality measurement devices. Importantly, assessment of lab VOC levels should use ppb to detect relevant levels.

Medical Gases

Sufficient supplies of medical gases like N₂ and CO₂ must be provided for all planned equipment inside the IVF lab. Nitrogen generators or liquid supply tanks for nitrogen or CO₂ may also be utilized in lieu of smaller gas cylinders. During the design phase, verify that a medical gas room of sufficient size to hold the required gas supply is located outside, but near the IVF laboratory. Proximity near a freight elevator and away from patient care areas is recommended for ease of delivery and avoidance of noise. The medical gas room should contain safety features like gas cylinder storage racks or cages, as well as an active atmosphere venting system. An oxygen alarm is also required.

Gas manifolds will be required inside the medical gas room; either manual systems or automatic systems. If automatic tank switchers are utilized, it is recommended these are connected to emergency backup power. Ensure master shutoff valves and pressure alarms are included and placed in key locations.

Braized copper piping is often utilized to supply laboratory gases, though welded stainless steel may also be used. Plastic tubing can suffice if supply pressure is not too high.

Low-pressure regulators and barbed fittings at the gas outlets inside the IVF laboratory are often recommended, as this permits supply of varying pressure requirements to different incubator models. Ensure gas outlets are placed near the location of incubators or other equipment requiring gas supply and at a sufficient height to avoid issues with installation of the equipment (low enough to fit beneath air tables or high enough to clear incubators, etc.).

Design Control

Functional laboratory design plans (a drawing or specification) describing all the components, equipment, and space requirement and should be reviewed and approved by the lab director or other person in charge of laboratory facilities. While a professional team of architects, along with a general contracting firm experienced in medical facility build out will have previous experience navigating complex local, federal, and international regulatory standards; they may not have experience with requirements or preferences for IVF laboratories. Regular meetings should be held with the construction company and contractors, and a detailed record of meeting minutes and plan revisions should be kept.

An integral part of design control is ensuring that the final product conforms to requested specifications. Reviewing the plans with the technologists, medical doctors, and staff who will be working in the space can help ensure the new design is fit for the intended use. Small but important details, like the placement of light switches and outlets for all necessary equipment for performing daily operations, can be easily assessed by the staff that use these items every day, and can be expensive to move or change after construction is complete. A person with lab expertise should review each set of designs/drawings and then monitor progress onsite via regular visits throughout the duration of the build to ensure that requirements are met. It is not uncommon for changes to be made during construction or for mistakes to arise and only through vigilant oversight will these be identified and corrected.

The design plans should include a lab floor plan that maps workflows and includes all lab equipment; maintaining close proximity between micromanipulation workstations and other IVF work stations to all incubators. Equipment lists and planned locations of instruments (with dimensions), placement of lights, air vents, electrical and IT outlets should be considered for each room.

If windows are present, ensure black out blinds are available to help regulate light/heat within the laboratory. Incubators and ICSI workstations should be protected from direct sunlight to avoid potential issues with light and/or temperature regulation.

Lab office space is often recommended to be adjacent to or connected to the laboratory with a doorway to separate to allow easy access, but avoid bringing unnecessary items into the main laboratory that could impact growth conditions.

Design should also consider confirm size of doors if large equipment will need to be installed, pathways of delivery to the lab, proper swing of doors to avoid collisions and optimize space utilization.

Equipment

The available number and quality of critical equipment and instrumentation, such as incubators and micromanipulators, can play a role in the success of an IVF program. For incubators, accurate case-volume estimates for the laboratory are critical, and should include low oxygen incubators that are utilized appropriately to avoid overcrowding. This may include separate units that are dedicated to storing culture media, oil and equilibrating dishes and units dedicated for embryo culture. Backup units or redundancy of critical equipment should be also considered (ICSI microscopes, lasers, incubators, fridges, freezers, etc.) to avoid disruption to the lab in the event of equipment failure.

Regardless of equipment choices, a regular laboratory equipment maintenance quality system schedule and documentation is required. This includes hoods workstations, incubators, centrifuges, pipette calibration/validation, and other small instruments.

Technical staff will be performing the same motions hundreds of thousands of times, day in and day out. Other equipment considerations should be ergonomics, providing technical staff with adjustable control of equipment, with tilting eye pieces, equipment with arm support, and adjustable seating as appropriate.

Quality assurance programs are predicated on the ability to rapidly identify and correct any nonconformance to set tolerance ranges. All incubators (CO₂ and temperature) and cryostorage vessels (liquid nitrogen levels) should be monitored by an alarm system with ability to email and/or call staff in case of an emergency. Additionally, natural gas or diesel backup power generators should be included in the laboratory design and sufficient for more than 8 h of backup power supply of all critical lab equipment, as well as other patient care areas. Generators should be certified initially with a 2 h load bank test, and serviced semiannually maintenance/inspections and yearly load tests. Occasionally, if a generator is not feasible, UPS units are required on all crucial equipment, with supply long enough to permit corrective action in case of a power failure.

Burn-In and Space Preparation

After construction is complete, the laboratory should be wiped down with an approved disinfectant/cleaner, such as 3% hydrogen peroxide, and the walls, floors, cabinets, and other surfaces should be wiped several times over the course of the entire burn-in period. It is necessary to move equipment into the lab and clean and test it with appropriate bioassays prior to clinical use. Of critical importance is the burn-in period for the lab incubators. Incubators should be cleaned according to manufactures instruction and temperature raised to greater than 45°C for several days or up to 2 weeks to promote off-gassing. The lab temperature can be raised to help with off gassing of other laboratory items.

The burn-in period should document on the lab's QC sheets that proper environmental conditions, that is, correct temperature, gas levels, and functioning of all equipment has been met for several days. Additionally, air quality testing should

measure VOC and particle counts pre and post burn in and the differences documented in the QC records. The air quality testing should be performed by a professional company or by lab personnel if hand-held particle counter and VOC meters have been purchased.

Ultimately, the burn-in period will conclude by checking pH and other growth condition parameters and pretesting all culture supplies with appropriate bioassays to ensure proper incubator conditions are met prior to clinical use.

Conclusion

Design and equipping of the laboratory is of paramount importance in help establish a successful IVF program. This begins with careful planning of workflow and design considerations. Constant oversight is then required to ensure proper materials are used and design specifications adhered to throughout the construction process. Careful selection of equipment is required, with proper use and maintenance. Validation of operation via a burn-in period is required with appropriate testing prior to testing patient samples.

© 2018 Elsevier Inc. All rights reserved.

Introduction

The ultimate goal of an IVF program is to help every infertility patient/couple achieve their dream of having a healthy child. While this might seem easy to accomplish, there are a considerable number of variables that play into the success of each IVF cycle (Fig. 1). On the one hand, there are the clinical variables including the genetic background of the man and woman, the environments to which they have been exposed which might affect their reproductive potential, their age, the manner in which the woman's ovaries are stimulated for oocyte (egg) collection, the efficiency of the oocyte retrieval, the expertise with which the embryo transfer is performed (Sigalos et al., 2017a, b) and uterine issues concerning establishment of pregnancy (Luke, 2017). On the other hand, there are numerous variables relating to the IVF laboratory, including the culture system used to maintain the cells in vitro, and the scope of technologies offered and the manner and standards to which they are performed (Gardner and Kelley, 2017).

The IVF laboratory should be considered as a highly complicated manufacturing plant in which the starting off materials, the oocytes (eggs) and sperm (i.e., the gametes), are brought together to result in the final product, the embryo. If preimplantation development proceeds normally, the embryo traverses developmental milestones from day 1 to day 6, from the 1-cell stage through to the hatching blastocyst stage, ultimately to implant around day 6.5 (Fig. 2).

As with any complex manufacturing plant, consistent assurance of product quality in the IVF lab is of paramount importance. Overlain on this principle of final product quality are three further challenges faced by an IVF laboratory. Firstly, most often gametes and embryos from several patients are under the care of an IVF laboratory simultaneously, therefore requiring a stringent policy for maintenance of identity of all samples from all patients at all times. There is absolutely no room for sample mix-up in an IVF laboratory. Secondly, in addition to this over-arching concern about patient safety, the IVF laboratory has the responsibility to maximize the inherent ability of all gametes and embryos at all times. The IVF laboratory is particularly challenged in this regard, given the

Fig. 1 Variables involved in the success of an IVF cycle. *IVF* = In vitro fertilization in which conventional insemination of oocytes is performed by adding sperm around the oocyte in the medium; *ICSI* = Intracytoplasmic sperm injection, in which a sperm is injected into an oocyte; *OA* = Obstructive azoospermia, a condition in which some portion of the male reproductive system is blocked, leading to absence of sperm in the ejaculate; *NOA* = nonobstructive azoospermia, in which there is no blockage, yet no sperm in the ejaculate.

Fig. 2 Flow diagram showing the time-line of preimplantation development of the human embryo.

sensitivity of these cells to their environment (Cohen et al., 1997). Thirdly, the IVF laboratory must ensure that all procedures are performed exactly to the orders of the physician. As IVF laboratory technologies continue to evolve, more and more combinations and permutations of technologies are available, which inevitably lead to greater complexity in patient management and greater possibility of error.

With the above issues in mind, an IVF laboratory must have a comprehensive quality management program (QMP) in place. This program, a total quality management plan (TQMP), must ensure consistency in performance and allow for continuous improvement within a systematic and safe paradigm. In the United States, the Clinical Laboratory Improvement Amendments of 1988 (CLIA 88) mandates that all laboratories implement a QM program that monitors and evaluates overall quality of laboratory services at all times (Boone, 1992). In addition, our professional societies, the Society for Assisted Reproductive Technology/the American Society for Reproductive Medicine, and the European Society for Human Reproduction each has guidelines for the operation and management of an IVF laboratory (Practice Committee of American Society for Reproductive Medicine, Practice Committee of Society for Assisted Reproductive Technology, 2008; Magli et al., 2008).

In this article, we first consider the challenges to maintaining a stable IVF laboratory; we then review how to maintain a stable IVF laboratory; and finally we discuss paradigms for performing trials focused on quality improvement.

Challenges to Maintaining a Stable IVF Laboratory

Differences Between In Vivo and In Vitro Environments

Although we often refer to the environments in the lumen of the reproductive tract as being “fluid” (i.e., Fallopian tube “fluid” and uterine “fluid”), in fact they are anything but, consisting of a complexity of macromolecules including proteins and carbohydrates, as well as extracellular vesicles, ions and RNA molecules (Zhang et al., 2017). Indeed, the in vivo environment and the in vitro culture systems differ strikingly in fundamental ways (Fig. 3) and so it is probable that all currently used culture systems are nonphysiological, and that even the best is likely suboptimal for embryo development (Sunde et al., 2016). Therefore, despite continuing efforts to improve our culture technologies, and the plasticity of the human embryo to adapt to its environment, everything must be done to maintain a stable and reliable environment in the clinical IVF laboratory.

The Complexity of Procedures Performed in a Contemporary Clinical IVF Laboratory

The scope of lab technologies available today contrasts strikingly with that used for the first successful IVF birth of Louise Brown in 1978. For that success, only one oocyte in a natural cycle was retrieved without hormone priming, and fertilization was achieved by adding sperm to the culture medium surrounding the oocyte; transfer of the resultant embryo was done about 48 h later, late on day 2 (Steptoe and Edwards, 1978). For in those days, concerns about the probable sub-optimal culture environment for human embryo development led to the dogma that the embryo(s) should be taken out of the incubator and put into the uterus as quickly as possible. In contrast, clinical IVF nowadays typically involves retrieval of several oocytes, the formation of a number of embryos from either conventional insemination or ICSI, and use of one or more of a variety of other adjunct procedures, including extended culture of the embryos to day 5 or beyond. The complexity of procedures performed in the contemporary IVF laboratory is therefore considerable (Fig. 4), which makes it all the more necessary to have an all-encompassing and effective TQMP.

Fig. 3 Comparison of some of the major differences between the in vivo and in vitro environments. Reproduced with permission of LifeGlobal LLC.

Fig. 4 The major procedures performed in the IVF laboratory. ICSI = Intracytoplasmic sperm injection, in which a sperm is injected into an oocyte; IVF = In vitro fertilization in which conventional insemination of oocytes is performed by adding sperm around the oocyte in the medium; PGT = preimplantation genetic testing, in which a few cells are removed (i.e., biopsied) from the embryo and are tested either for a known genetic mutation, or for the number of chromosomes present.

Sensitivity of the Cells Handled in the IVF Laboratory

Human gametes and embryos are exquisitely sensitive to any environmental perturbation including temperature fluctuations, light exposure, changes in the hydrogen ion concentration in the medium (measured by the acidity of the medium, known as the pH) and overall air quality (Boone et al., 1999; Hall et al., 1998). This is particularly the case for oocytes. For example, within minutes of only a 4°C drop in temperature, disassembly occurs of the meiotic spindle, the minute structure on which the chromosomes are held and aligned (Wang et al., 2001). Although the spindle re-polymerizes after recovery of the temperature, risks of error in chromosome realignment occur. Therefore, the importance of ensuring stable temperature control as a key component of maintaining a stable laboratory environment cannot be over-emphasized.

How to Maintain a Stable IVF Laboratory

As indicated in Fig. 5, there are numerous aspects to maintaining a stable IVF laboratory, which together fall into the three general principles and activities of quality control (QC), quality assurance (QA) and quality improvement (QI). All three principles are inter-related such that one independently is of no value without the remaining two. Each of these principles must be applied for protocol development and then for constant implementation and assessment of performance to ensure continuous stability of the laboratory.

Fig. 5 The aspects and activities involved in running a stable IVF laboratory. QC = Quality Control; Insem = conventional insemination of oocytes, in which sperm are added to the medium surrounding the oocyte; Eval/Selec = Evaluation and Selection of embryos for transfer; Cryo = Cryopreservation, in which the embryos are frozen.

Quality Control (QC)

Quality control involves the collection of data that reflect the performance of the laboratory. To this end, data must be recorded that enable control for the effectiveness of methods, equipment, supplies, testing personnel and the environment to ensure the safe and efficacious function of the laboratory to the highest possible standards. Examples of key metrics for quality control in the IVF laboratory are shown in [Table 1](#). The data collections are undertaken at regular and defined intervals to prevent any ongoing problems that may lead to compromise in patient care ([Keck et al., 2009](#)). Of particular importance in this regard is the monitoring of the culture incubators, as any fluctuations in gas composition of the incubator atmosphere or the temperature of the machines can have disastrous results. Indeed, each incubator must be monitored daily, with successful operation being dependent on additional instrumentation including gas tanks, alarm systems, back-up power generators and the devices used to calibrate and measure the incubator settings. Activity logs are typically used in which acceptable ranges of performance are stipulated for each measured parameter ([Table 2](#)). All QC activities are run simultaneously with procedures to ensure that lab performance can be linked to clinical outcomes ([Boone et al., 2010](#)).

Quality Assurance (QA)

Quality assurance (QA) is the over-arching activity involving analysis of the data collected through QC and assessment of all other measures critical to appropriate running of a stable IVF laboratory. Through these comprehensive analyses, assurance is obtained that the protocol, equipment, supply/product, testing personnel and the environment are all performing within established targets and therefore performing to spec. The data analyses should be regular so as to catch any issue that may impact patient care in a timely fashion, whether this involves an equipment malfunction or subpar performance of an embryologist performing a particular procedure. In our laboratory, our standard key indicators of performance (KIPs) are the fertilization rate and the percentage of high quality of embryos on day 3 and day 5. Monitoring fertilization rate is particularly useful as it provides real-time insight into any variance in laboratory performance and one does not have to wait for weeks to see

Table 1 Key metrics for quality control in an IVF lab

<i>What</i>	<i>Action</i>
Protocols	Protocols written with regularly updates, and verification that personnel have read, understand and know them
Instrumentation performance	Recording performance of specific parameters (e.g., temperature at defined intervals)
Personnel performance	Adequate training and certification sign-off. Competency evaluations undertaken through external and internal proficiency testing
Patient data	Recording of key performance indicators (KIPs) with preidentified targets of performance. Standard KIPs in clinical IVF are: fertilization rates, embryo quality, and implantation rates
Environmental control	Recording of daily measures of air quality contaminants (e.g., particulates, CO ₂ , VOCs)
Patient identity (safety)	Documentation that two patient identifiers are on all samples. Documentation of use of checklists at key check points (e.g., oocyte retrieval, insemination, and transfer) to ensure patient safety
Supply inventory control	Documentation of dates that supplies are received, opened and expired, and documentation of suitability for use in clinical IVF with bioassay testing

Table 2 Incubator QC activity log

<i>Parameter</i>	<i>Frequency</i>	<i>Target</i>	<i>Acceptable Range/Supply</i>	<i>Corrective action</i>
CO ₂	Daily while in use	Based on recommended pH of Culture Media	±1% to achieve target pH	Adjust when out of range for two consecutive days
O ₂	Weekly	5%	±1%	Adjust when out of range for 2 consecutive days
Humidity	Daily while in use	95%	≥ 80%	Add sterile water
Temperature	Daily while in use	37°C	36.7°C–37.0°C	Adjust when out of range for two consecutive days
pH	Weekly	Based on media specifications	Based on media specifications	Adjust CO ₂ when out of range for two consecutive days
Alarm check	Monthly	Email and phone notification	100% coverage of alarmed instrumentation	Contact technical support
CO ₂ Tanks	Daily	Full back-up supply	> 1500 psi in primary tank	Order new tanks
Liquid N ₂	Daily	Full back-up supply	≥ 1 back-up tank available	Order new tanks
N ₂ tanks	Daily	Full back-up supply	≥ 1500 psi	Order new tanks
1-Cell mouse assay	Semi-annual	≥ 70% Blastocyst development	≥ 70% blastocyst development	Clean and sterilize incubator, repeat mouse assay

if pregnancy rates have been compromised. As with any KIP, acceptable targets should be set and a performance chart (p-chart) used to monitor performance. Fig. 6 shows the p-chart for weekly embryo quality rates (as assessed by the % of embryos having at least 7-cells on day 3) in our laboratory for 2106.

In addition to data analyses, other measures that are considered under the rubric of QA include maintenance of comprehensive and up-to-date laboratory protocols (with sign-off by testing personnel at least annually), evaluation of continuing medical education of testing personnel, integrity of result reporting, and auditing of treatments to ensure that the treatments performed reflect the orders made. Examples of key QA activities performed in an IVF laboratory are shown in Table 3. The overall purpose of QA is to ensure stable laboratory performance through constant surveillance that allows either confirmation of acceptable performance (obviously the desired result) or identification of any problems or errors that can then be dealt with through corrective action.

Quality Improvement

Quality improvement (QI) is the process undertaken to improve some specified aspect of laboratory performance. This may relate to the introduction of a new protocol, a new procedure to perform an established protocol or a new supply (Boone et al., 2010). Regardless, the IVF laboratory handles material that is irreplaceable, so great care must be taken to ensure that any such introduction will not compromise patient safety.

Establishment of written protocols for QC, QA, and QI are just the beginning of the process to ensure adequate quality management and maintenance of a stable IVF laboratory. Continued technical monitoring and improvement needs to be in place at all times. One way to do this is to perform mock cases or peer observations (Bormann and Racowsky, 2012). In mock cases, all aspects of the laboratory processes are performed by each staff member who is certified to perform those tasks. Protocols should be followed as if these were real cases. These mock cases will help identify problems that can be corrected before errors with clinical specimens occur. Peer observations play a similar role in which one embryologist observes another embryologist performing a task on a live case. Both members know the protocols and the task should be completed exactly as per written protocols. If there is a drift from the protocol, action can be taken to identify the drift as being detrimental to the process or not. If the drift is considered detrimental, steps need to be taken to ensure the written protocol is followed. If the deviation has a positive impact, steps can be taken to implement the new process among all team members. The more frequent the monitoring, the quicker the negative deviations are identified and eliminated and the more rapidly the positive ones are implemented. Due to the critical nature of all work in the IVF laboratory, failure at any juncture of the process has dire consequences. Therefore, the processes have to be airtight and unwavering at all times.

Fig. 6 An example of a performance chart for weekly embryo quality rates. This chart shows the percentage of embryos that reach at least to the 7-cell stage on day 3, which we have found gives a reliable guide of overall laboratory performance.

Table 3 Key quality assurance activities in the IVF lab

<i>What</i>	<i>Action</i>	<i>When</i>
Data review of instrumentation performance	Perform daily cross-checks and verifications that instruments are performing within acceptable targets for all measures	Daily
Data analyses	Analysis of collected data for Key Performance Indicators (KIPs) with preidentified targets of performance	Defined by the KIP: weekly for fertilization and embryo quality data; monthly for implantation rates
Personnel performance	Assessment of performance against identified metrics and against targets set in external and internal professional education activities	A minimum of twice annually
Environmental control	Monitoring of air quality with identified maximum targets of acceptability for individual measures (e.g., particulates, CO ₂ , VOCs etc.)	Weekly
Alarm monitoring	Monitoring of all culture incubators and frozen storage vessels	Daily, 24/7 with a rapid-response system in place; e.g., using an alarm phone tree
Patient identity (safety)	Identify checkpoints for identification and implementation of check-lists and double sign-offs. Use of mock cases to ensure patient safety. Confirm two patient identifiers on all samples. Perform mock cases with laboratory team to ensure safety	Before each patient sample is handled
Supply inventory control	Establish a supply management protocol for appropriate storage and stock rotation, and a method for quality control of supplies (e.g., using a mouse embryo bioassay to assess embryo development, or a sperm motility assay to assess motility after exposure to the new supply)	Before implementation in the IVF lab
Frozen tissue inventory control	Assurance of accurate log-keeping of tissue identity and location of all frozen oocytes, sperm, embryos, and ovarian tissue	Ongoing inventory inspection and verification of content and location at least annually

The Plan-Do-Check-Act Cycle

The central dogma of a total quality management plan demands continuous improvement of the systems and processes that will result in improvements in the product and/or services provided. In the case of the IVF laboratory, the TQMP helps improve the success of couples taking home a healthy child. There are many models that can guide setting up a strong TQMP. One that is used widely in many fields is the “Plan-Do-Check-Act” or PDCA Cycle or Shewart or Deming Cycle (Mortimer and Mortimer, 2005) (Fig. 7). The PDCA Cycle is based on the scientific method, and is a well-established simple model that can be implemented to monitor the laboratory’s performance and make quality improvements where needed (Bormann and Racowsky, 2012).

- *Plan*: In this step one looks at the current state of the processes and looks for areas for improvement. If a problem is identified, as much information as possible is gathered and an educated hypothesis is formed regarding possible causes. In this step, one needs to set objectives and processes to reach targeted outcomes; therefore it is wise to set measurable and attainable goals and, if possible, test the hypothesis on a small scale.
- *Do*: In this step, the plan is executed. Criteria are set for the studies, which are implemented on a trial basis to test the hypothesis. Data are collected for analysis during which all team members understand the changes implemented and that are being assessed.
- *Check*: In this step, the data collected from the previous step are analyzed. The effectiveness of the changes implemented is checked by looking at key performance indicators established in the Plan. Also, verification is done that the Plan was completed

Fig. 7 The plan-do-check-act (PDCA) cycle. An approach used in a total quality management program to maintain and improve performance in a complex environment. Published with permission from Ginsburg, E.S. and Racowsky, C. (eds.) *In Vitro Fertilization: A Comprehensive Guide*. Springer: New York-Heidelberg-Dordrecht-London.

appropriately and there was no deviation from the Plan. Was the plan validated with the desired goals achieved? If so, the next step is undertaken. If not, the Plan and Do steps may need to be refined.

- *Act:* In this final step of the cycle, all of the differences from the actual and planned results are assessed. If the changes implemented showed an improvement, then these become the new standard and are implemented on a broader scale. If the results did not show an improvement, the current practice remains in place. These changes will be continuously monitored for possible improvements in a future PDCA cycle.

Patient and Tissue Identification

Patient safety in the IVF lab is of the upmost importance. This concept encompasses not only assurance that all patient samples at all times are maintained in appropriate conditions. Equally importantly, safety also incorporates the concept of patient and tissue identification. The IVF process is very stressful for the couple experiencing infertility. They are relinquishing their control in this intimate process to the highly trained staff of the IVF laboratory. They rely on the staff to make sure that the upmost care is taken to ensure that their gametes maintain their true identities. Unfortunately, albeit at exceedingly low frequencies, nightmarish scenarios have occurred such as transferring embryos to the wrong patient, insemination of oocytes with the wrong sperm (Pomeroy and Racowsky, 2012) and the mislabeling of embryos (Newman, 2000). In such circumstances, root cause analyses have indicated that there were major breakdowns in the sample identification process. The greatest fear in every IVF couple's mind is the possibility that their gametes or embryos are mixed up. This same fear is shared by every IVF laboratory and all checks and balances must be in place and implemented at all times to avoid such a disaster.

- *Rules and regulations governing patient and tissue identification:* Rules and regulations concerning the proper identification of patients and collection and handling of specimens should be part of any IVF manual. The College of American Pathologists (CAP) accredits IVF laboratories in the United States and this organization has a specific set of procedures in the General and Reproductive Laboratory Checklists that should be followed by all US IVF laboratories. One of the most important of these regulations is the requirement to have unique patient identification. This must be accomplished by having a minimum of two identifiers used to distinguish each patient and her specimens. This could be a combination of any number of the following: name, date of birth, medical record number, social security number, accession number, etc. In our lab, we use the patient name and a unique identifier comprised of the date of the oocyte retrieval (or oocyte or embryo thaw), followed by the order of the procedure that day. For example, if Jane Smith is the first patient to have her oocyte retrieval on August 22, 2017, her two identifiers would be [Smith, J and 082217-1]. In conjunction with patient identification, policies must be in place governing chain-of-custody of all specimens and safety pauses at critical steps such as oocyte retrieval, insemination, embryo biopsy, and embryo transfer. Two embryologists should sign off on all patient identifiers at these critical steps.
- *Protocols needed for airtight identification:* Airtight identification of patients and specimens is essential at all steps of the IVF process. Each lab needs to develop its own protocols to identify safety checkpoints based on the staffing and make-up of the lab that governs the day to day flow of laboratory operations. An excellent reference to identify the flow of the lab is the textbook by David Mortimer, "Quality and Risk Management in the IVF Laboratory" (Mortimer and Mortimer, 2005). This book contains flowcharts that can help identify points in the IVF process at which proper identification of patients and specimens is absolutely critical. Once the critical steps are identified (Table 4). The laboratory can write protocols and establish checklists to maintain the

Table 4 Steps in the IVF laboratory requiring patient and tissue identifications

Procedural step		Suggested identification steps			
Male ^a ID before sample collection	Patient ID with a government issued ID	Male signs verification of sample use	Male labels collection cup with ID		
Sperm sample hand-off to lab personnel	Patient ID at sample drop-off	Cup label verification	Chain of custody sign-off	Lab receiving	
Sperm preparation	Cup ID verification	Gradient tube ID	Wash tube ID	Final preparation ID	
Oocyte collection	Time out (i.e., surgical pause) for patient ID	Retrieval tubes ID	Retrieval dishes ID	Insemination dish ID	Incubator ID
IVF	Incubator ID	Sperm ID	Insemination dish/oocyte ID	Incubator ID	
ICSI	Incubator ID	Egg cleaning ID	ICSI dish ID	Sperm ID	Incubator ID
IVF Fertilization check	Incubator ID	Fertilization dish ID	Wash dish ID	Culture dish ID	Incubator ID
ICSI Fertilization check	Incubator ID	Culture dish ID	Incubator ID		
Embryo grading	Incubator ID	Culture dish ID	Incubator ID		
Assisted hatching/biopsy	Incubator ID	Culture dish ID	Incubator ID		
Embryo transfer	Patient ID	Culture dish/embryo ID	Transfer dish ID	Incubator ID	
Cryopreservation	Straw ID	Cane ID	Freeze dish ID	Incubator ID	Culture dish ID

^aID = Identification; two identifiers must be used at every identification step and two embryologists must sign off on both identifiers.

chain-of-custody and proper identification of each patient and sample. Checklists used at critical points of the IVF process are an extremely useful tool in reducing or eliminating procedural drift and the possibility of errors. (Gwande, 2009; Bormann, and Racowsky, 2012). Four critical steps in the general IVF process at which checklists are recommended are: sperm receiving/processing, egg retrieval, insemination and embryo transfer. An example of a template for the checklist for embryo transfer is shown in Fig. 8.

CHECKLIST FOR EMBRYO TRANSFER

(Embryologist participating in the transfer must check all boxes and initial below to confirm check completion)

Patient ID Sticker	Partner ID Sticker
--------------------	--------------------

HOOD SETUP

- ☐ Hood surface and microscope stage area clean
- ☐ Dissecting microscope turned on with oculars and focus adjusted ready for use
- ☐ HEPES pre-warmed in Inga placed in ER hood warming block
- ☐ Stripper pipette with new tips at hand
- ☐ Embryo transfer dish labeled with last name and Case ID

DATA RECORDING AND INCUBATOR CHECK

- ☐ Information relating to number of embryos to transfer recorded
- ☐ Patient name and Case ID on dishes confirmed

PREPARATION OF EMBRYOS FOR TRANSFER

- ☐ Cross-check link between label identifiers on home incubator and Name and Case ID on data record sheet
- ☐ Re-confirm Patient name and Case ID on transfer dish
- ☐ Confirmation of Embryo ID documented on data record sheet

PREPARATION OF EMBRYO PHOTOS

- ☐ Patient ID Sticker placed on each of the 2 photos
- ☐ Correct Patient ID Sticker name confirmed by 2nd embryologist

SURGICAL PAUSE

- ☐ Visual confirmation of patient ID from her hospital bracelet against the patient identifiers on the data record sheet
- ☐ Verbal confirmation with patient name and number of embryos to transfer as documented on data record sheet
- ☐ Documentation of presence of embryologist at surgical pause on data record sheet
- ☐ Documentation of confirmation of patient ID on data record sheet

PROCEDURE

- ☐ Visualization of patient name and Case ID by embryo transfer physician
- ☐ Hand-off or embryo transfer catheter loaded with embryo(s) to transfer physician
- ☐ Confirmation of absence of embryo in catheter immediately after transfer by rinsing the catheter
- ☐ Documentation that transfer completed on data record form

Initials: _____ // _____
 Transfer Embryologist 2nd Embryologist

Fig. 8 A template for a checklist used before and after an embryo is transferred into a patient. *ID* = Identification.

Trials Focused on Quality Improvement

The IVF laboratory is faced with two main challenges when testing a product or evaluating a protocol that may improve lab performance. First, human gametes and embryos are more sensitive than those of other species to environmental perturbations so use of animal tissue for product evaluation has limited utility. Second, accepting the premise that human gametes and embryos should be used for evaluation of any potential improvement, the evaluations have to be done with extreme care, recognizing that any compromise to patient care must be kept to an absolute minimum. In general, IVF laboratories will undertake a QI trial in two phases. In the first phase, samples are randomized within patients to the test condition or to the standard condition. If no adverse effects are observed in phase I and/or a benefit is suggested, the second phase is performed in which the patients themselves are then randomized.

Randomization of Samples Within Patients

In this design, the oocytes or sperm or embryos of each patient are randomized to one of two conditions and outcome variables are identified. For example, we might be interested in testing a new culture medium for growing embryos that has just come on the market. In this case, embryos on day 1 are typically randomized (by a coin toss or using a randomization numbers table) to the standard, currently used medium or the new medium and embryo development is assessed. The advantages of this design are (1) that any potential compromise to patient care is ameliorated because only a percentage of her cells are being exposed to the “test” medium; and (2) as the patient is serving as her own control, a matched paired analysis can be performed, thereby enabling a “cleaner” comparison between the two groups. The main disadvantage of this design is that only those embryos with a known outcome after transfer (i.e., either as implanted or not) can be included when analyzing developmental ability; in cases in which two embryos were transferred with one from the control and one from the test condition but only one implanted, it is unknown which medium can be attributed to the “implanter” so these cases have to be excluded.

Randomization of Patients

In this design, the patients themselves are randomized to the two conditions so that all the embryos from each patient are cultured either in our standard medium or in the new test medium. The advantage of this approach is that all transferred embryos are included in the analysis. However, disadvantages include (1) the time required to recruit a sufficient number of patients to demonstrate significance; and (2) possible harm to patients if any risks have not been identified in a phase I trial as described above.

Summary

Unlike most fields of medicine, the IVF laboratory plays a rather unique role in the management and treatment of patient care. For the physician team is dependent on a quality of IVF laboratory to provide the highest quality of care to their patients, while the laboratory staff are dependent on the physician team to bring in patients for their livelihood. It is therefore critical that the clinical and laboratory staff work in close collaboration with collegial and open communication to ensure that the ultimate goals of the IVF program are met at all times, for every single patient. To ensure that this synergistic clinical/laboratory rapport is successful, there must be trust on both sides, but particularly that the IVF laboratory is stable and providing the highest standards of patient care. To this end, the IVF laboratory must utilize a comprehensive and effective TQMP. All checks and balances must be in place to assure not only that effective QC and QA protocols are adhered to and updated, but also that a QI program is established that focuses on introducing improvements to patient care. All aspects of the QM program must be effectively managed through, for example, utilization of the PDCA cycle. With such systems in place, patient safety and identification will be assured at all times and the stability of the IVF laboratory will be maintained thereby ensuring that the developmental capabilities of all cells received are maximized.

The Preparation of Sperm

Denny Sakkas, Boston IVF, Waltham, MA, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

The preparation of sperm for infertility treatment was initially introduced for intrauterine insemination techniques. As far back as the 14th century there are accounts of Arab peoples using artificial insemination on horses. Even in the 3rd century AD, records show that Jewish thinkers were discussing the possibility of accidental or unintentional human insemination by artificial means. The first attempts at human artificial insemination by John Hunter are believed to have occurred in 1785, with a baby born the same year. Early reports of donor insemination were published in the *British Medical Journal* in 1945, and in 1955, four successful pregnancies using previously frozen sperm were reported. With the advent of in vitro fertilization (IVF) and the treatment of more complex male infertility cases the preparation of sperm has evolved.

Semen Analysis and Sperm Preparation

It is commonly accepted that the standard World Health Organization (WHO) criteria for sperm number, motility, and morphology are a good, although not always perfect, indication of a male's fertility status. The current criteria (WHO, 2010) have undergone various changes from the 1999 to 2010 WHO recommendations, whereby semen volume [2–1.5 mL], sperm concentration [20–15 million per mL], progressive motility [50%–32%], and normal forms [14%–4%] have all been decreased respectively. Although the current criteria suggest a certain volume, number, motility, and morphology it must be emphasized that this is an indication that the male may have difficulties to father a child rather than predicting fertility. For the preparation of sperm in cases of IVF, it is more a matter of maximizing the quality of sperm you prepare rather than the initial count in the semen. Furthermore, with the advent of intracytoplasmic sperm injection (ICSI) harvesting thousands or even millions of sperm is not always necessary.

This article will give a broad review of current laboratory technologies and procedures for the routine preparation of sperm from the semen.

Traditional Preparation of Semen Samples for IVF

Semen samples are routinely obtained from the male by masturbation into a sterile container. It is recommended for the male not to have ejaculated for 2–3 days prior to collection. This however is now coming under question. A recent study (Alipour et al., 2017) examined whether a short abstinence period of only 2 h yielded spermatozoa with better motility characteristics than samples collected after 4–7 days. They found that even though a significantly lower semen volume, sperm concentration, and total sperm counts in all motility subgroups is obtained, the significantly higher percentage of spermatozoa with better motility characteristics (velocity, progressiveness, and hyperactivation) in the second ejaculate, may provide and allow for a simpler and more effective selection of higher quality spermatozoa.

Preparation

For the purposes of an IVF cycle, a simple count and motility screen is normally sufficient, as the aim is to prepare the sperm for treatment rather than for diagnosis. Once collected, the semen is allowed to liquefy for up to 30–45 min. It can then be prepared using either a swim-up (SU) technique or by density gradient (DG) centrifugation. Sperm preparation for assisted conception by DG centrifugation routinely uses 0.5–1 mL volumes of a 40% suspension layered over 0.5–1 mL of a 90% suspension of a colloidal silica suspension in an isotonic salt solution mixed in human tubal fluid (HTF) media or a similar commercial media. Semen is overlaid on the 40% and 90% layers (Fig. 1) and then centrifuged for approximately 20 min (300g). Sperm in the 90% pellet are harvested, washed in HTF media and then stored in an incubator until use. Gradient systems use solutions with a higher density than semen to separate the debris, cells, microorganisms and nonmotile sperm from the motile ones. Cellular debris and nonmotile microorganisms will be trapped at the interphase between the two solutions. Among the dense solutions used are colloidal silica (Percoll, Puresperm), poly-sucrose (Ficoll, Ixaprep), and other dense solutions (Optiprep, Nycodenz). It is generally thought that the DG preparation will select more normal sperm than the swim-up method because it has a specific density of approximately 1.1 g mL^{-1} , however recovery may be poor in viscous semen and severe teratozoospermia, in particular when many small headed sperm are present as they will not be de-selected.

The swim-up method requires centrifugation of the ejaculate to form a pellet followed by layering of clean medium (0.5–1 mL) over the pellet (Fig. 1). The sperm are then allowed to swim freely up into the clean portion and are then harvested. This technique relies on the ability of the sperm to swim. This method is suitable for semen with high to moderate motility. Briefly, the semen is generally diluted with 1:2 ratio of culture medium and centrifuged at 250–300g for 5–10 min. The supernatant is removed leaving

Fig. 1 Comparison of swim-up and density gradient for preparing sperm samples.

the pellet. The pellet can then either be layered under clean media or clean media can be carefully layered over the pellet. The tube is then left to stand for between 30 and 60 min at a 45 degree angle, which creates a larger surface area for sperm to swim-up. Once finished the clean media is taken up carefully without disturbing the lower layer and transferred into a new test tube. If a number of tubes are prepared per patient then to concentrate the sperm, the tubes can be pooled and centrifuged at 250–300g for 5–7 min. The supernatant is removed and the resultant pellet resuspended in 0.4 mL of media.

Finally, if the semen sample is very poor and no or only one to two sperm are seen during the analysis a simple wash can be prepared. This will mainly remove seminal plasma from the sample. One volume of semen is placed in a 15 mL test tube and diluted with twice the volume of culture medium. The tube is gently inverted to mix the components and then centrifuged at 250–300g for 5–10 min. The supernatant is removed and the pellet is resuspended in 2 mL of culture medium. Centrifugation can be repeated again if no sperm are seen. The pellet is then resuspended in about 0.4 mL of clean media. The same wash procedure is suitable for intracervical insemination.

The question of whether swim-up or density gradient provides a better sample has been scrutinized in many studies (Ng et al., 1992; Sakkas et al., 2000; Palini et al., 2017). In general, studies have shown that both are efficient in providing good sperm preparation. Recently Zhao et al. (2016) reported no significant difference between the DG and SU procedures, showing that both methods had lower DNA fragmentation, reactive oxygen species content, and sperm progressive motility. They also showed that sperm telomere length was improved with both techniques. In some other recent studies the argument has been made that swim-up is easier to perform and may improve pregnancy rates when used in comparison to DG.

Insemination and Intracytoplasmic Sperm Injection (ICSI)

Once the sample is prepared, the total motile sperm concentration is calculated using the volume and number of motile sperm. Insemination can then be performed by adding a predetermined amount to the droplet of culture medium containing the cumulus enclosed oocytes. Oocytes can be inseminated in groups or individually in droplets of embryo culture medium with between 50 and 500,000 motile sperm mL^{-1} overnight. Insemination is routinely performed between 1300 and 1500, allowing incubation overnight. There are some indications that embryo quality is improved when clinics have utilized a short insemination period (Kattera and Chen, 2003; Gianaroli et al., 1996) whereby the sperm are introduced for a period of 1–4 h only and then the oocytes are removed. With this approach, the oocytes are not exposed to radical oxygen species and other possible harmful factors generated by the large population of sperm overnight. If the sperm preparation is substandard in number and/or motility or if the patient has previously been identified to have fertilization issues then they will be a candidate for ICSI.

ICSI is now chosen as the standard method of insemination. Current rates of ICSI utilization in the USA are close to 70% of cycles. This has led to investigating whether it is over-used. A recent paper showed that routine insemination may actually yield more fertilized eggs on the whole when compared to ICSI (Boulet et al., 2015). Other concerns with ICSI still remain, in particular, with respect to its safety. Current data however indicates that children born after ICSI have not shown any differences when compared to children born from routine IVF or natural conception (Bonduelle et al., 1996; Leunens et al., 2008; Belva et al., 2011).

Relating Sperm Preparation With Sperm Analysis Methods

It is now becoming more apparent that sometimes a simple sperm preparation as a whole is not sufficient. The preparation method is therefore being tied in more and more with some type of sperm analysis which results in sperm selection. The most notable of these selection and preparation methods is the hyaluronan (HA) binding assay. The HA binding test ([Sbracia et al., 1997](#); [Huszar et al., 2006, 2007](#); [Jakab et al., 2005](#)) test provides information about the maturity of the sperm. Briefly, human sperm that bind to HA exhibit attributes similar to that of zona pellucida-bound sperm, including minimal DNA fragmentation, normal shape, and low frequency of chromosomal aneuploidies ([Cayli et al., 2003](#); [Celik-Ozenci et al., 2003](#); [Jakab et al., 2005](#)). In preliminary results from a multicenter clinical trial, it was shown that when patients with less than 65% binding efficiency are screened and selected before ICSI, their success rates are improved by incorporating HA binding in their treatment ([Worriolow et al., 2012](#)).

Other sperm preparation technologies are also being developed. Magnetic activated cell sorting (MACS) of apoptotic sperm is based on the availability of colloidal superparamagnetic microbeads (50 nm diameter) conjugated with annexin V able to bind to phosphatidylserine residues (reviewed by [Said et al., 2008](#)). This technique has been utilized to separate dead and apoptotic spermatozoa ([Grunewald et al., 2001](#); [Lee et al., 2010](#); [Said et al., 2008](#)). Sperm cells are labeled with annexin-V magnetic beads and passed through a column, which is placed in the magnetic field of a MACS separator.

Reports have described the use of these techniques and the achievement of the first newborns. To date the data presented are limited, and there are few studies adequately addressing the benefits of MACS to improve clinical take home baby rate by selecting nonapoptotic sperm cells compared with standard sperm selection methods ([Dirican et al., 2008](#); [Polak de and Denaday, 2010](#); [Rawe et al., 2010](#)).

The other more promising technology is that of microfluidics to prepare sperm. This was initially introduced by Smith and colleagues ([Schuster et al., 2003](#)). Numerous groups have now started to introduce its use in IVF laboratories ([de Wagenaar et al., 2015, 2016](#); [Shirota et al., 2016](#)).

Of the numerous other methods investigated sperm membrane charge has also been used to enable better sperm preparation. Two methodologies are the Zeta potential ([Chan et al., 2006](#)) and an electrophoretic chamber ([Aitken et al., 2011](#)). Although the electrophoretic chamber appears promising ([Ainsworth et al., 2007](#)), neither has been tested to see if they convey significant clinical improvement. Unfortunately, of all the techniques developed to date there is no clear sperm preparation technique that has provided conclusive evidence of improving efficiency when compared to SU or DG.

Conclusion

IVF reproductive technologies have come a long way since the first birth in 1978. The technical progression from routine insemination to ICSI for treating many male infertility patients has changed the way we prepare sperm. It is now coming to light that the role of the paternal genome in influencing the success of IVF is more subtle than once thought ([Sakkas and Alvarez, 2010](#); [Jenkins and Carrell, 2012](#)). We are subsequently realizing that more effort should be made in sperm preparation techniques and many research laboratories are now putting more effort in developing novel methods for sperm preparation and selection.

EMBRYOLOGY

Oocyte Treatment From Retrieval to Insemination

Laura Francesca Rienzi, Benedetta Iussig, and Filippo Maria Ubaldi, G.EN.E.R.A. Centres for Reproductive Medicine, Rome, Italy

© 2018 Elsevier Inc. All rights reserved.

A Brief Overview of Multifollicular Growth and Oocyte Retrieval

While the initial attempts of assisted reproductive technologies (ART) were conducted on spontaneous menstrual cycles, nowadays controlled ovarian hyperstimulation (COH) is widely used to stimulate multifollicular growth in order to increase oocytes availability for in vitro fertilization. This is accomplished with the administration of a cocktail of exogenous human gonadotropins from the early follicular phase to achieve supraphysiologic levels of circulating FSH, widening the so called “FSH window” and allowing to override the single dominant follicle selection (Pacchiarotti et al., 2016).

Follicular growth is then constantly monitored with ultrasound serial measurements of follicular size and determination of circulating estradiol concentration. When the follicles reach an appropriate stage of development, ovulation is induced with a surrogate LH surge, which stimulates the resumption of meiosis (consisting in the germinal vesicle-GV-breakdown and the consequent oocyte progression to the metaphase II-MII-stage), the retraction of corona cells processes and the mucidification and expansion of the cumulus cells layer (Russell and Robker, 2007).

While in spontaneous menstrual cycles the ovulated oocytes are then captured by fimbriae and released in the Fallopian tubes, during assisted reproductive treatments they are directly removed from the follicular microenvironment by means of surgical harvesting. The technical details of oocytes retrieval differ between centers, but basically it is performed transvaginally inserting a fine cave needle with ultrasound guidance to the ovaries and aspirating the follicular content by means of an external vacuum pump which modulates the aspiration pressure. Usually, this procedure is scheduled 34–36 h after ovulation triggering in order to avoid premature ovulation and subsequent cycle cancellation.

Don't Disturb the Gamete: Working Conditions

The follicular fluid containing the oocytes is collected into sterile tubes connected to the aspiration system (Fig. 1), then passed to the adjoining laboratory for further analysis. Any handling of the biological material outside the controlled environment of the incubators should be performed with extreme care.

The oocytes are susceptible to light exposure, so that this should be maintained to a minimum. Sunlight is the worst stressor to both oocytes and embryos, and even prolonged exposure of mammalian oocytes and embryos to ordinary cool or warm white fluorescent light is inadvisable. Incandescent light from the illuminators of ordinary optical microscopes would not produce any serious problem unless used excessively (Takenaka et al., 2007; Oh et al., 2007).

During the entire manipulation procedure, efforts should be made to minimize even transient temperature fluctuations that may have detrimental effects on oocyte developmental competence: in fact, only few minutes at room temperature cause meiotic spindle depolymerization, thus potentially increasing the risk of aneuploidy (Pickering et al., 1990). Temperature control can be easily

Fig. 1 Follicular fluid collected in a sterile tube during oocyte retrieval. All the tubes must be labeled with patient information and identification number in order to guarantee unambiguous identification.

accomplished using warmed surfaces and devices and limiting the time in which the biological material is kept at a temperature minor to 37°C. Since temperature is dispersed by plastic ware, it is recommended to calibrate the heated stages to a higher temperature, around 37.5–38°C.

Another key factor to keep controlled during manipulation outside incubators is pH. Intracellular pH (ipH) is necessary to maintain intracellular homeostasis. Since it is influenced by extracellular pH (epH), it is fundamental to maintain the optimum media pH relatively stable (Swain, 2010). This can be accomplished first limiting the time of manipulation under atmospheric conditions (low CO₂ concentration determines a rapid rise in the extracellular pH) and, secondly, guaranteeing fast oocyte relocation in an appropriate culture system (Swain 2010).

Finally, some authors found that dissolved oxygen levels during follicular aspiration and oocyte retrieval rise rapidly (Redding et al., 2006). Even if the precise O₂ level under natural conditions is still unknown and may be developmental stage-dependent, it is now ascertained that low oxygen level should be a principle for all mammalian embryo culture systems including humans. In fact, it has been proved to be beneficial with a significant increase in the number of newborns (Bontekoe et al., 2012). Since it takes more than 5 h for the oxygen to fall to oocyte and embryo safe levels, it is important to protect the culture from O₂ rising as well limiting once again air exposure.

Cumulus-Corona-Oocyte Complex Identification and Grading

Once in the laboratory, the follicular fluid is handed over to the embryologist, who pours it in prewarmed sterile plastic dishes in order to examine it carefully (Fig. 2). The follicular fluid contains many free granulosa cells, which derive from the follicle walls and are organized in amorphous clumps, and the cumulus-corona-oocyte complexes (CCOCs), the structures formed by the cumulus cells and the enclosed oocyte (Figs. 3 and 4). The entire CCOC identification procedure is performed under a laminar flow hood, at the stereomicroscope, which produces a three-dimensional visualization of the sample. The identified CCOCs are then cautiously transferred with a Pasteur pipette in an appropriate culture medium and cultured in incubator (humidified atmosphere, 37°C, 5%–6% CO₂, low oxygen tension) till conventional insemination, intracytoplasmic sperm injection (ICSI) or cryopreservation.

CCOC assessment generally represents the first line evaluation in the everyday work of an average IVF laboratory. Among cumulus cells (CCs), two different entities can be recognized: inner and outer cumulus cells, which differ for sensitivity and responsiveness to external stimuli. The innermost layer is also called “corona radiata”: it contacts the oocyte thanks to trans-zonal projections (TZPs) that form gap junctions with the oolemma, establishing a bidirectional communication fundamental for both follicle and egg growth (Albertini et al., 2001). At the time of oocyte retrieval, 34–38 h after ovulation triggering, oocytes are supposed to have reached full nuclear maturity (MII stage). The cumulus-corona mass of fully mature oocytes is expected to be highly expanded as a consequence of the secretion of hyaluronic acid, that interposes among the cells and separates them conferring to the complex a fluffy appearance (Testart et al., 1983). On the contrary, unexpanded compact CCs usually enclose immature oocytes, at the prophase (Germinal vesicle stage, GV) or metaphase stage of the first meiotic division (MI).

During the years there have been different attempts to define a grading system for objective and standard classification of cumulus-corona-oocyte complexes (Rienzi et al., 2011). The most applied criteria were those proposed by Lin et al. (2003), who produced a quite complete CCOCs evaluation scheme. In their proposal, CCOCs are divided in five different groups based upon detached granulosa cells (GCs) aspect, cumulus expansion, corona radiation and ooplasm features. In detail, the “mature” CCOCs are constituted by well-aggregated membrane granulosa cells, expanded cumulus, radiant corona, distinct zona pellucida

Fig. 2 Follicular fluid poured in a Petri dish during the CCOC identification procedure. All the dishes must be labeled with patient information and identification number in order to guarantee unambiguous identification. The embryologist works under flow laminar flood and manipulates the biological material with extreme care, paying particular attention to the maintenance of the correct culture conditions such as light exposure, temperature, pH and oxygen tension.

Fig. 3 Cumulus-corona-oocyte complex visualized at 100 $\times$ magnification. The cumulus mass is expanded and it is possible to identify the associated oocyte. Although not visualized in this particular focal plane, a first polar body is present in the perivitelline space. The ooplasm is clear.

Fig. 4 Cumulus-corona-oocyte complex visualized at 100 $\times$ magnification. The cumulus mass is compact and dark GCs clumps are diffused. The associated oocyte is dark, obscured by the cells, and its precise maturational status is uncertain.

and clear ooplasm. On the contrary, “immature” CCOCs present compact and nonaggregated GCs, compact dense cumulus mass, adherent compact corona layer and presence of a germinal vesicle in the ooplasm (if visible). However, between these two CCOCs classification patterns, it is possible to identify one intermediate class, the so called “approximately mature,” characterized by expanded, well-aggregated membrana GCs, expanded cumulus mass but slightly compact corona. During oocyte pick-up, it is also possible to retrieve “postmature” CCOCs, with small and relatively nonaggregated membrana GCs, expanded cumulus with clumps, radiant corona radiata (yet often clumped, irregular or incomplete), visible zona pellucida and slightly granular or dark ooplasm. Finally, “atretic” CCOCs are composed by GCs with very small clumps of cells, rarely associated cumulus mass, clumped and very irregular corona radiata (if present), visible zona pellucida and dark and frequently misshapen ooplasm.

Notwithstanding, it has been suggested that in stimulated cycles cumulus expansion and CCOCs evolution doesn’t always run parallel to oocyte nuclear maturation, as observed in natural cycles, maybe because of a different sensitivity of the oocyte and the CCs to the stimulants, resulting in an asynchrony between the two processess ([Laufer et al., 1984](#); [Bar-Ami et al., 1989](#)).

More recently, the Alpha Scientists in Reproductive Medicine and the European Society of Human Reproduction (ESHRE) Special Group of Embryology concluded that, to date, there’s little evidence to support the role of CCOCs morphological analysis in the prediction of oocyte maturity and competence. As a consequence, the application of a simple binary score to define expanded CCs and radiating corona (point 1) ([Fig. 3](#)) or compact cumulus mass (point 0) ([Fig. 4](#)) appears more suitable for the purpose ([Alpha Scientists in Reproductive Medicine and ESHRE Special Interest Group of Embryology, 2011](#)).

Conventional In Vitro Insemination

After CCOC identification, the oocytes can be inseminated through conventional insemination or intracytoplasmic sperm onjection (ICSI). In the first case, no more CCOC manipulation is required, since the CCOCs are incubated in the presence of a defined

concentration of motile spermatozoa. On the contrary, in the case of ICSI, it is necessary to remove the cumulus cells surrounding the oocytes (denudation) prior to perform injection.

Insemination timing should be decided evaluating the time elapsed from ovulation triggering and/or oocyte retrieval, assuming that a preincubation period may be beneficial for the accomplishment of complete oocyte maturation: normally, this correspond to 38–40 h after ovulation triggering or 3–4 h after oocyte retrieval (Ho et al., 2003).

Mature pre-ovulatory CCOCs are transferred with a Pasteur pipette to a convenient culture support, the choice of which is a matter of preference. Two main culture systems are commonly used: petri-dishes presenting microdrops of culture media under oil or, alternatively, four-well plates. In both cases, it is possible to culture the CCOCs singularly or co-culture them in small groups of 2–3 CCOCs. Whichever the culture system of choice is, it is advisable to use equilibrated media, preincubated in an incubator at 37°C, 5%–6% CO₂, low oxygen tension for a suitable period. Moreover, it is recommended to trace all the batches used for media as well as for any plastic support, in an effort to guarantee quality monitoring (ESHRE Guideline Group on Good Practice in IVF Labs, 2016).

The CCOCs are routinely inseminated exposing them to a prepared sample of progressively motile spermatozoa, the number of which must be optimized in order to increase the chance of normal fertilization. Normally, this corresponds to a concentration ranging between 0.1 and 0.5×10^6 progressively motile spermatozoa per ml (ESHRE Guideline Group on Good Practice in IVF Labs, 2016). It is recommended to suspend the final sperm preparation in a culture medium compatible with oocyte culture and fertilization, preferably containing glucose in order to allow sperm function (ESHRE Guideline Group on Good Practice in IVF Labs, 2016). Two different operators should check the correspondence of the gametes used, in order to guarantee their identity and to avoid hazardous mismatching.

The CCOCs-sperm suspension is then incubated overnight in incubator (humidified atmosphere, 37°C, 5%–6% CO₂, low oxygen tension) till the fertilization check, usually performed 16–18 h after insemination (Alpha Scientists in Reproductive Medicine and ESHRE Special Interest Group of Embryology, 2011).

Oocyte Denudation

Opposite to conventional insemination, oocytes need to be denuded before performing sperm microinjection. The term *oocyte denudation* refers to the removal of the somatic cell layers that surround the oocytes. These cells are forming during the preovulatory growth, within the follicle. The oocyte will be surrounded by two different cell layers: *granulosa and thecal cells* that sustain oocyte nutrition and maturation providing essential metabolites, hormones, and growth factors (Fig. 1); all of it driven presumably by the oocyte which directs its own development as well as the follicle differentiation (Maggiulli et al., 2012; Albertini et al., 2001).

During oocyte pick up, oocytes will be aspirated from the preovulatory follicle environment and a new structure called cumulus oocyte complex COC will be obtained (Fig. 2). The COC is composed of the secondary oocyte, which should be arrested at metaphase II, surrounded by a multilayer of specialized granulosa cells called cumulus cells. They possess highly specialized trans-zonal cytoplasmic projections that pierce through the zona pellucida and form gap junctions at their tips with the oocyte (Albertini et al., 2001). The gap junctions will allow paracrine factors and low molecular weight factors to freely travel in both directions (Canipari, 2000; Feuerstein et al., 2006).

The timing between oocyte retrieval and oocyte denudation varies between different laboratories. Based on the on the ESHRE Guidelines for good practice in the IVF laboratory, the consensus was to wait for a consistent time interval of 4 ± 1 h between the time of trigger and the time of cumulus cell removal (de Los Santos et al., 2016).

What is commonly accepted is that a preincubation period in the incubator at 37°C and 5% CO₂ of at least 1 h is unavoidable. Rienzi et al. (1998) studied different preincubation timings concluding that a preincubation period between oocyte retrieval and ICSI of at least 3 h can improve the fertilization rate and embryo quality. This period might be necessary for some oocytes to reach full cytoplasmic maturity, leading to a higher activation rate upon microinjection. On the other hand, too long preincubation timings (in this case established as more than 9 h), resulted in embryos of lower quality (Rienzi et al., 1998). However, this can varies depending on different women's ranges of age, prospective randomized studies would be needed.

Oocytes are very vulnerable to fluctuations on temperature and pH (Swain, 2015; Swain et al., 2016; Will et al., 2011).

Before denudation, the presence of cumulus cells may provide to the oocytes a protective action against pH changes due to the presence of gap junctions. However once they are removed, the oocytes will be more sensitive. It has been shown that human oocytes have very limited capacity to combat alkalosis. On the other hand, the acidosis will require energy to be battled from the oocyte, consequently both alkalosis and acidosis should be avoided to decrease the stress at which the oocytes are exposed.

Concerning temperature, two aspects have to be taken into account, the actual temperature that will be achieved and the duration of the oocytes to be exposed to room temperature. Among the possible negative effect of temperature drops to room temperature such as impact of embryo metabolism, and embryo cleavage rate, others like the meiotic spindle stability and chromosome dispersion deserves special consideration (Pickering et al., 1990; Almeida and Bolton, 1995; Wang et al., 2001).

Fig. 1 Diagram showing the distribution of the oocyte and the cells surrounding it after oocyte retrieval.

Fig. 2 Image of a cumulus oocyte complex after oocyte retrieval.

Fig. 3 ASTEC Smart Station is an integrated IVF Work Station which substantially enhances the working environment for IVF procedures.

For example, the exposure of oocytes to 34°C for 10–30 min decrease approx 20% the spindle recovery rate affecting fertilization ability as well. If the exposure is at room temperature, less than 50% of spindles will recover (Pickering et al., 1990).

Hence, the step of denudation has to be performed avoiding variations in both parameters. Handling conditions to allow a stable environment of 37°C and adequate CO₂ to control for pH are highly recommended. Laboratory settings using cabinets as shown in Fig. 3 are a very good option. Other approaches such as the use of buffered media and heated working surfaces may be used as well if the first option is not available.

The removal of the surrounding cumulus cells is achieved by a combination of both enzymatic and mechanical treatment.

Enzymatic Treatment

The egg released from the ovarian follicle is surrounded by the cumulus mass. Before ovulation takes place, in concomitance with oocyte maturation, LH induces some transformations in this cumulus cells. In response to this gonadotrophin the cumulus cells produce specific glucosaminoglycans, the secretion of which results in cumulus mucification and its expansion. The major component of the extracellular matrix secreted by the cumulus cells is hyaluronic acid.

Because of this, hyaluronidase is employed for enzymatic removal of these cells. This enzyme digests the hyaluronic acid interspaced between the cumulus cells (Mahadevan and Trounson, 1985). Until now, few studies have tested the possible effects of different concentrations of hyaluronidase in sibling-oocytes. The initial concentration used of this enzyme was established in 760 IU/mL, but it was found that this concentrations were too high and induced a high percentage of parthenogenetic activation of the mature oocytes. At the moment, the commonly used concentration of this enzyme in most IVF laboratories is 80 IU/mL. However, Van de Velde et al. developed a study that showed how a concentration as low as 10–8 IU/mL hyaluronidase can be used successfully to denude oocytes for microinjection (Van De Velde et al., 1997; Moura et al., 2017).

Mechanical Treatment

The enzymatic treatment is also helped by a mechanical action. The procedure needs to be carried out very gently to avoid any mechanical damage in the oocytes. Pricking of the oocyte has been shown to induce parthenogenetic oocyte activation (Iritani, 1991).

Once the oocytes have undergone the enzymatic contact with the hyaluronidase, changes in the diameter of the pipettes used are crucial for a final denudation.

To start with, the COC is too big and diameters of approximately 190 μm are required.

Once the enzyme has acted, a decrease in the diameter of the capilar to approximately 130–150 μm is needed, because the oocyte will still have some cells attached which can make it difficult to evaluate the final maturation. This smaller diameter needs to be used in clean drops of culture medium because oocytes should not spend more than 1 min in contact with the hyaluronidase. This critical timing and the knowledge of this critical step in the laboratory has been crucial to decide in our clinic that the maximum number of oocyte denudated in each dish has to be eight despite our experience as embryologists, and even less for embryologists with less experience.

Briefly, the dishes used in our laboratory to proceed to the decumulation of oocytes are shown in the Fig. 4.

In the Fig. 5 we illustrated two different ways of proceeding to oocyte denudation by two different embryologists in our laboratory basically based in a different organization or direction of the oocytes throughout the droplets.

The rationale behind the oocyte denudation before microinjection is to see the maturation stage of the oocytes in order to distinguish between those that suitable for being microinjected or not, or even to select some of them for in vitro maturation because in the presence of cumulus, visualization of the oocyte is very limited.

In addition to meiotic status, the morphology of the oocytes is also evaluated before ICSI being able to detect some abnormalities that may affect fertilization rates and embryo quality. This is important for embryologists to have more information especially in order to explain patients in cases where the results are not positive.

One of the key events that necessarily need to take place for successful fertilization is the resumption of meiosis in the oocyte. Although the majority of the oocytes (80%–90%) will be at metaphase II, since ovulation has been triggering, oocytes can be found at different maturation stages (Fig. 6).

Fig. 4 Diagram showing the distribution of different drops in the dish and how oocyte denudation is performed.

Fig. 5 Diagram showing different ways of performing oocyte denudation by different embryologists in our laboratory.

Fig. 6 Images of oocytes in different maturation stages.

Germinal vesicle (GV)

In this stage, oocytes are meiotically arrested. These are immature oocytes where a typical nuclear structure is perfectly visualized and are not used for microinjection.

Throughout the infancy of women, oocyte stay in this stage. When puberty arrives and women start with menstruation, at each cycle one (or rarely more) oocytes reinitiate the meiotic division.

Metaphase I

Meiosis has been reinitiated with what is known as the vesicle breakdown (GVB), however the appearance of the first polar body has not taken place yet.

With the reinitiating of meiosis the chromosomes condense and align on the newly formed meiotic spindle, and the pairs of homologous chromosomes segregate between the oocyte and the first polar body.

Metaphase II

All of the events have occurred and we have a mature fertilizable oocyte, completed at the metaphase of the second round of meiosis.

After checking for oocyte maturation status, ICSI will be performed on those oocytes that are presumably at metaphase II because the presence the first polar body (more detailed information about the ICSI procedure will be available on the upcoming chapters). However, we should always bear in mind that only by visualizing the meiotic spindle with the use of polarized light microscope, which evaluates the oocytes' spindles according to birefringence of living cells, can assured the maturation status of oocytes (Montag et al., 2006).

Eventually immature oocytes could be used for clinical purposes. In humans, in vitro maturation (IVM) occurs in 30%–50% of oocytes recovered from non-stimulated cycles (Cha et al., 1991) and in 60%–80% of germinal vesicle (GV) oocytes removed from stimulated ovaries (Goud et al., 2000; Escrich et al., 2011). An average of 75% of the denuded GV oocytes recovered from stimulated cycles matured spontaneously to MII during a period of 42.7 ± 2.4 h (Escrich et al., 2011) they can be fertilized and give live births although with low rate of efficiency.

Introduction to Assisted Fertilization

When the oocyte is fertilized by sperm “outside” of the body, it is called “in vitro” fertilization or assisted fertilization (Stephoe and Edwards, 1978). Robert Edwards together with Patrick Steptoe were the first to achieve a successful live birth in 1978 via “in vitro” fertilization using the “conventional insemination” procedure (Stephoe and Edwards, 1978). A little less than two decades later, in 1992 an alternative insemination procedure was developed, called intracytoplasmic sperm injection (ICSI) (Palermo et al., 1992). These break through procedures followed decades—and even centuries of research/experiments on reproductive physiology, summarized well in the review by Clarke (Clarke, 2006). After the successful introduction of IVF in United Kingdom, very soon other countries also implemented the procedure and its use increased exponentially leading to an estimated 5 million babies born by 2015 thanks to assisted reproduction.

Conventional insemination was the only procedure performed in the “early days” of IVF (as no “viable” alternative approaches existed at the time); where oocyte(s) retrieved from follicle(s) in a natural or in a stimulated cycle were placed in a Petri dish and were mixed together with the processed sperm received from the male partner. Gametes were usually left in place for overnight to allow the sperm to enter the egg and initiate the fertilization. While this insemination procedure usually provided good fertilization and adequate outcomes for couples with no “male-factor” infertility, it frequently resulted in low or failed fertilization where sperm parameters were suboptimal (low concentration and/or low motility and/or low morphology).

Assisted Fertilization by Intracytoplasmic Sperm Injection (ICSI) and by Intracytoplasmic Morphologically Selected Sperm Injection (IMSI)

Due to the inconsistent or poor results with conventional IVF with mild and severe male-factor cases there was a need for a new type of insemination technique, using microinjection. There have been many different approaches explored to assist fertilization of oocytes, both in animal models and in human. Among the more studied options were partial zona dissection (PZD) and subzonal injection (SUZI), none providing significant improvement in oocyte fertilization. ICSI has also been investigated initially in animal models, however, it resulted in an extreme high degeneration rate typically when using rodent gametes (for review on the different microinjection techniques, please see the publication from van Rumste et al., 2000). Intriguingly, human gametes appeared to provide much better outcomes than it was observed in animal models, and when applied clinically, the first pregnancies were reported from the Brussels University (AZ-VUB) in 1992 (Palermo et al., 1992). Since its introduction, the use of ICSI has rapidly spread across the globe, and today it is used as a preferred way of oocyte insemination, frequently also in nonmale factor cases as it provides a more “secure” way for fertilization (Palermo et al., 2015).

Oocyte and Sperm Preparation for ICSI and IMSI

Timing of oocyte collection is typically performed 35–37 h after ovulation trigger. Cumulus and corona radiata cells have to be removed which is done by combination of enzymatic digestion (using hyaluronidase) and mechanical “stripping”, 2–3 h following egg retrieval.

Oocytes then observed by an inverted microscope at $\times 200$ magnification for nuclear maturity and for other morphological characteristics. Only those oocytes that are mature (i.e., extruded the first polar body) will be inseminated by ICSI or IMSI.

Sperm preparation is typically performed using a discontinuous gradient centrifugation (there are alternative options, including the more “historical” swim-up procedure) (Van der Zwalm et al., 1991). The aim of sperm preparation is to produce a clean suspension of motile sperm in culture medium that is compatible with both sperm and oocyte survival and fertilization. For ICSI, the prepared sperm is kept in suspension in a plastic tube until the microinjection procedure. For IMSI, a small aliquot of washed sperm is deposited into the IMSI dish (Fig. 1). The prepared sperm suspension will swim-out in a long “snake shape” drop before selection and oocyte injection. For IMSI, because more time needed for sperm selection, it is advised that sperm preparation is performed prior to oocyte retrieval.

Timing and Process of ICSI and IMSI Insemination

ICSI is usually performed 39–41 h after ovulation trigger (3 to 5 h after oocyte retrieval). Timing of microinjection relative to cumulus-corona cell removal does not seem to effect outcomes, however, most IVF programs will denude oocytes close to ICSI insemination. Microinjection of oocytes is carried out on the heated stage of the microscope using Hoffman Modulation Contrast System (as the best fit for plastic dishes) at $200\times$ or $400\times$ magnification. The microscope is typically equipped with coarse

Fig. 1 Sperm selection with Nomarski DIC optics (2A) and oocyte Injection (2B) on the Hoffman ICSI microscope (2B).

positioning and hydraulic control (for fine movements) micro-manipulators, which are essential for microinjection (see Fig. 2). For ICSI, a single sperm is selected from the sperm-PVP drop of the ICSI dish (see Fig. 3) and aspirated in the injection pipette after breaking the sperm tail. Following, the oocyte is visualized and secured with the holding pipette, while the ICSI pipette is pushed through the zona pellucida, inside the cytoplasm, until membrane is broken, then the sperm is released inside the oocyte (see Fig. 4). For a more detailed description of ICSI set up and ICSI procedure, please, see publication from Joris et al. (1998).

Timing and process of IMSI insemination is somewhat different from ICSI insemination, as sperm selection takes longer. When several IMSI have to be performed, especially with severe oligo-teratozoospermia, the selection of spermatozoa and injection are performed on two different microscopes. On one microscope, that is equipped with Nomarski DIC optic, morphologically normal spermatozoa are first selected and isolated in micro-drops. Then oocyte injection is performed afterwards on the second microscope that is equipped with Hoffman modulation contrast (see Fig. 2). Alternatively, selection and injection of maximum two oocytes at a time are performed exclusively on the IMSI platform (using only one microscope). This approach is preferred when a previous MSOME (motile sperm organelle morphology examination) showed sufficient morphologically good quality semen so that the selection process would be less time consuming.

Sperm Selection for ICSI and IMSI

Sperm for ICSI is selected on the inverted microscope using $200\times$ or $400\times$ magnification, immediately right before performing microinjection. Most critically, a motile sperm should always be selected for ICSI (the only exception is when sperm has to be recovered from testicular tissue). It has been demonstrated that selecting/using nonmotile sperm for ICSI has a strong negative impact on outcomes, while any other basic sperm parameters have much less influence on results (Nagy et al., 1995). In the last decade, there have been several studies that aimed to improve results of ICSI using different methods of sperm selection. Those investigations include: annexin V magnetic activated cell separation (MACS), glass wool filtration; electrophoresis (surface charge based selection); hyaluronic acid binding (sperm “maturity” assessed by membrane characteristics). For details on the different sperm selection techniques, please, refer to the following reviews (Said and Land, 2011; Rappa et al., 2016).

Sperm selection for IMSI is based on high magnification evaluation of sperm morphology. Sperm morphology can be best assessed after fixing and staining the sperm cells (as it is done for semen evaluation), however, those sperm can no longer be used for microinjection. In order to counteract the problem of morphological evaluation on stained spermatozoa or with complex and high-tech systems; Bartoov (Bartoov et al., 2001) introduced in 2001 a new innovative noninvasive technique for a more precise morphological evaluation of motile spermatozoa in real time. With the use of Nomarski differential interference contrast optics (DIC), the so-called “motile-sperm organelle-morphology examination” (abbreviated as MSOME) changed the perception of how a viable spermatozoon suitable for injection should appear. The morphological characteristics of motile sperm nucleus

Fig. 2 Typical ICSI microscope (inverted), equipped with two coarse positioning manipulators (3D Motor Driven Coarse control Manipulator) and with two three-dimensional hydraulic remote-control micromanipulators. The holding and injection pipettes are fitted to a tool holder and are connected by Teflon tubing to a micrometer-type microinjector. The center of the microscope stage is heated to maintain physiological conditions during ICSI procedure.

Fig. 3 Typical ICSI dish. Sperm is placed to the center drop (3–5 μL), which contains polyvinylpyrrolidone to slow down the sperm motility. The four side drops are HEPES buffered embryo culture drops (5–10 μL), where oocytes are placed. The drops are covered with paraffin oil to prevent evaporation from the drops.

according to the shape and chromatin content was defined. Particularly the fine morphology of the sperm head proved to be of major interest, namely fine nuclear abnormalities visible as craters, hollows or concavities which were defined as vacuole-like structures (VLS) are better detected and were identified as an abnormal, “thumbprint”-like nuclear concavity conferring an indirect representation of a pathological situation. Morphologically normal spermatozoa (class I) are selected using glass bottom dishes on an inverted light microscope equipped with Nomarski differential interference contrast optics (DIC), with dry or immersion $63\times$ or $100\times$ magnification objectives lens (corresponding to $630\times$ or $1000\times$ magnification in contrast to the $200\times$ or $400\times$ magnification with the “traditional” ICSI).

Fig. 4 ICSI procedure. The sperm is delivered deep inside the cytoplasm of the oocyte by the ICSI injection pipette, after passing through the zona pellucida and breaking the oolemma. Oocyte is kept in place by the holding pipette during the ICSI procedure.

Molecular Aspects of Vacuole Like Structure (VLS): Tangible Arguments to Select Sperm Free of Nuclear Defects

Since the implementation MSOME to assess sperm morphology, we are more anxious about the presence of large VLS and consider them as potential defects (Boitrelle et al., 2011). One crucial question to investigate is if VLS are the morphological manifestation of nuclear dysfunction. Undeniably, sperm carrying VLS were found to be related to nuclear dysfunction in terms of lower mitochondrial potential, loss of DNA integrity, higher aneuploidy rate and consistently related with chromatin condensation problem (Boitrelle et al., 2011; Perdrix et al., 2011). Anomalies of sperm chromatin packaging and abnormal chromatin remodeling during sperm maturation may impact DNA methylation levels. Indeed, the importance of re-packaging of the haploid genome before delivery in the oocyte is a crucial step for the establishment and maintenance of a viable pregnancy. By analyzing sperm DNA methylation and RNA transcripts in spermatozoa, a recent study showed the paternal contribution and the crucial role of sperm epigenetic in embryonic development (Kumar et al., 2013). Even though the indications for MSOME and the usefulness of IMSI are still under debate, the importance of selecting normal sperm free of VLS becomes obvious if epigenetic defects could be related with the presence of VLS. Epigenetic modifications in mature spermatozoa play an important role and may alter methylation profiles with the risk of fertilization failure, dysfunction of embryogenesis, preterm birth, low birth weight, congenital anomalies, autism, perinatal mortality (Schagdarsurengin et al., 2012). These altered methylation errors are subsequently transmitted to the embryo, conferring a potential risk of imprinting disorders to the offspring and for the next generation. It has also been observed that DNA methylation levels are significantly lower in normal spermatozoa compared with the group of spermatozoa carrying VLS. Out of these preliminary studies, we may assume that hypermethylation, source of epigenetic defects could be related with sperm morphology and presence of VLS.

Laboratory and Clinical Outcomes With ICSI Insemination

It has been demonstrated from the beginning, that ICSI insemination offers outstanding clinical and laboratory outcomes for patients who have male-factor infertility and/or had failed conventional insemination/IVF. Because of the excellent results with ICSI, intracytoplasmic sperm injection was fast adopted for routine use across the world. Furthermore, ICSI insemination today is used much more frequently than conventional/IVF insemination, and there are a number of IVF centers, where ICSI is the only technique used for insemination (to avoid occasional fertilization failure after conventional insemination, which can happen, even if sperm parameters are in the normal range). It has been demonstrated, that using ICSI, none of the basic sperm parameters have strong influence to the outcomes (Nagy et al., 1995), with the only exception of necrozoospermia (in which cases testicular biopsy is recommended to recover living sperm). The only other condition when ICSI results may be impaired is in the cases of total globozoospermia (or round-headed spermatozoa, which is a rare type of teratozoospermia characterized with multiple structural abnormalities, including the lack of acrosome). While ICSI is a more secure way than conventional insemination to obtain fertilization, — occasional fertilization failure can happen with ICSI too. In a study, analyzing 2732 ICSI cycles, total fertilization failure was observed in 76 cases (2.8%), however, most of those cases had an extreme low number of oocytes obtained, or immotile sperm or round-headed sperm (thus fertilization failure may not be because of the technique itself) (Liu et al., 1995).

Obstetrical and perinatal outcomes after ICSI have not raised concerns according to most studies published on the topic—despite that initially there were questions raised on intrinsic risks due to the technique. One of the argument was that ICSI is an “invasive” procedure which can damage the oocyte or some of its organelles (like the spindle) resulting either in degeneration of the oocyte, or possibly abnormal embryo development (or causing chromosomal alterations). A potentially confounding factor is that ICSI when used in male-factor infertility, the patient population itself may contribute to certain conditions observed in offspring. One example is when son(s) of fathers with strongly impaired sperm parameters are much more likely to have decreased sperm values as well.

When examining the incidence of fetal chromosomal anomalies, most studies observed a slightly (but significantly) higher rate of abnormalities (Gjerris et al., 2008). It is mostly agreed, that the slightly higher rate of prenatal chromosome anomalies after ICSI is likely related to the patient population requiring ICSI, and not due to the technique itself (Bonduelle et al., 2002).

Incidence of major malformation on children born after ICSI showed no difference compared to what was observed in the IVF or in the general population (Bonduelle et al., 1996). In a prospective study, a 2.6% rate of major congenital malformations was reported (23 out of 877 children born) (Bonduelle et al., 1996), however, some other studies observed a somewhat higher frequency of hypospadias and cryptorchidism (Massaro et al., 2015). More recent studies analyzing high number of patients, and also meta-analyses have not shown a meaningful increase in the incidence of birth defects of “ICSI children” (Yan et al., 2011; Lie et al., 2005), again suggesting, that the increased risk, if any, it is more likely being associated with the patient population and not the technique itself. Some studies looking at development and health of ICSI children at early ages, observe some differences in the health of children, but this is likely connected to the age (and other health/medical conditions) of the woman (and man) receiving the ICSI treatment (Belva et al., 2007; Fauser et al., 2014).

Regarding clinical outcomes following IMSI, there is not much information in the literature, as IMSI is a much more recently developed technique, and it is also not used very frequently. However, it is important to emphasize that animal data are absolutely unequivocal on this point and clearly indicate that DNA damage in the male germ line is potentially hazardous for the embryo and therefore for the resulting offspring. According to a recently published paper, sperm nucleus morphological normalcy, assessed at high magnification, could decrease the prevalence of de novo major fetal malformations in ICSI children (Cassuto et al., 2014).

ICSI or IMSI?—Potential Indications for IMSI

One of the most essential questions is not under which technical conditions the selection of spermatozoa should be recommended but rather if we have to consider to select the best morphologically normal spermatozoa and, if possible, excluding those carrying defects. But, for different reasons, there is undeniable evident skepticism about this method of spermatozoa selection. Originally, the platform to perform MSOME and IMSI was provided not only with an inverted microscope equipped with Nomarski differential interference contrast Optics and condenser, but, in addition, with a high definition digital video camera and a variable zoom lens that magnify the microscopic image up to 12,000× magnification. With such technical approach, a lot of professionals from the ART world claimed that IMSI is a nightmare because it is expensive, complicated to perform, time consuming, and finally for no specific indication. At the present, the easiest and most convenient way to perform MSOME in combination with ICSI is to use only an inverted light microscope equipped with Nomarski differential interference contrast optics, at 63× or 100× magnification objectives lens. After several years, the superiority of IMSI over ICSI is still a matter of debate and even to date randomized and well-powered studies to confirm a benefit of IMSI are limited and even depict conflicting results (Perdrix and Rives, 2013).

One of the main benefits of IMSI is the higher rate of blastocysts obtained per cycle when morphologically good quality spermatozoa are selected (Knez et al., 2013). Nowadays, with successful verification techniques, the full benefit of a better spermatozoa selection is highlighted, if we are able to produce more blastocyst per cycle giving the chance for the patient to achieve a pregnancy in successive vitrified-warmed embryo transfer cycle(s). It has also already shown that IMSI improves reproductive outcomes in cases of male factor infertility and/or previous failed ICSI attempts in terms of implantation and clinical pregnancy rates as compared with conventional ICSI (Nadalini et al., 2009). On the other hand, IMSI and conventional ICSI seemed to provide comparable laboratory and clinical results when an unselected infertile population was evaluated (De Vos et al., 2013). Semen quality might be more important with advancing maternal reproductive age,—a group of patients that have important relevance in ART. If we assume that a majority of nuclear defects reflected in vacuoles may be correlated with DNA integrity, we may have a more optimistic view in the sense that this damage brought into the zygote by the fertilizing spermatozoon may be effectively repaired by oocyte factors from young and/or good-quality oocytes (Gunes et al., 2015). Even though oocytes can repair sperm DNA damage; a threshold exists beyond which sperm DNA cannot be repaired. This mainly depends on the degree and the type of sperm DNA damage (single-stranded versus double-stranded damage). Also, oocytes whose DNA repair mechanisms are not functional (aging oocytes—in vitro culture conditions) or that have been damaged by endogenous (e.g., free radicals) or exogenous (e.g., radiation, environmental toxicants) factors might not be able to repair this damage. This is a strong argument in favor of an accurate sperm selection when we have to inseminate oocytes obtained from patients with advanced reproductive age.

Summary

Intracytoplasmic sperm injection (ICSI) was successfully introduced in the clinical practice in 1992, to overcome male-factor infertility and in failed conventional IVF cases. Today ICSI is used across the world in most IVF cases, for almost all indications of

infertility. ICSI has demonstrated highly consistent outcomes at the level of fertilization (frequently more reliable than conventional insemination), embryo development, and obtaining high rates of implantations and pregnancies. Importantly, it was also demonstrated, that ICSI outcomes are not influenced importantly by traditional sperm parameters, thus great results can be achieved even in the most extreme cases of male factor infertility, where virtual azoospermia or total astheno- or total teratozoospermia was diagnosed in the initial semen sample (from the ejaculate). Only one condition had a strongly negative influence on the result of ICSI, where immotile (presumably dead) spermatozoon was injected into the oocyte. Additionally, ICSI can be applied successfully also when fresh or frozen-thawed epididymal and testicular spermatozoa are used.

Recent studies indicated, that ICSI outcomes may be further improved if the sperm selected for microinjection is examined under very high magnification for morphological characteristics. This lead to the introduction of IMSI which provided the advantage for embryologists to realize that more attention has to be paid during sperm selection even in case of classical ICSI. The application of IMSI leads to more and potentially higher quality embryos/blastocysts and as a consequence it increases the chance to select the proper embryo for transfer with the highest implantation potential. The full benefit of using MSOME as an additional tool to ICSI procedure manifests itself when it is performed in combination with extended embryo culture of all fertilized oocytes.

Seeing that this simple, noninvasive technique still arises debates and skepticism exists about its efficiency, mainly due to a low number of controlled randomized studies published yet, one fundamental question is whether we should—with the knowledge that sperm vacuoles are related with abnormal chromatin packaging and possibly with DNA fragmentation—select spermatozoa with these defects for injection if we have only to change the optics? As far as we know, there is no reason for not selecting the morphologically best spermatozoa.

In Vitro Maturation of Oocytes

Roger Hart, University of Western Australia, Perth, WA, Australia; and Fertility Specialists of Western Australia, Claremont, WA, Australia

Melanie Walls, Fertility Specialists of Western Australia, Claremont, WA, Australia

Introduction

In the process of in vitro maturation of oocytes (IVM) oocytes are collected from a patient in an immature form, in a procedure similar to a standard in vitro fertilization (IVF) cycle oocyte retrieval procedure. In some instances, only a short duration of ovarian stimulation is performed and the immature oocytes collected are matured in the laboratory.

IVM was first performed in a human model, after animal experiments, by Bob Edwards in 1965. Oocytes were collected from unstimulated follicles after ovarian biopsy and spontaneously matured, and the first live birth was recorded in 1991, after oocyte collection of oocytes from unstimulated ovaries and culture in follicular fluid (Cha et al., 1991). The first birth subsequent to IVM after transvaginal oocyte retrieval occurred in 1994 (Trounson et al., 1994). However since these early successes with IVM were not been generally embraced by reproductive medicine physicians, perhaps due to the perceived poor success rates of the procedure, perceived difficulties in cycle management, and the challenging laboratory processes involved; however with improvements in the protocols excellent pregnancy rates began to be achieved (Junk and Yeap, 2012). However a consistent challenge has been the inability to achieve satisfactory endometrial preparation, hence many groups transferred multiple embryos, and other adopted an embryo freezing approach, to try to maximize pregnancy rates (Walls et al., 2015b).

In view of the increased safety and success rates of IVF in recent years the place of IVM as a fertility treatment has been questioned. The purported benefits of IVM are; that it avoids (or significantly reduces) the amount of drugs used for ovarian stimulation, oocytes can be collected earlier in a menstrual cycle for a woman who requires to rapidly proceed to a cycle of chemotherapy treatment, it completely avoids the risk of ovarian hyperstimulation syndrome (OHSS) (a serious cause of morbidity for a woman undergoing IVF), and for a woman with an estrogen sensitive tumor or a significant pro-thrombotic tendency it avoids the risk of high concentrations of oestradiol (Walls et al., 2015b).

Clinical Place of IVM

The ideal patient for an IVM protocol is a young woman with a high antral follicle count, such as found in a woman with polycystic ovary syndrome (PCOS); as such women are particularly at risk of OHSS, and IVM avoids this risk completely. Similarly, a young woman about to embark on cancer treatment which may compromise her subsequent fertility, particularly if she has an estrogen sensitive tumor, is ideally suited to undergo IVM treatment; as it avoids the high oestradiol concentrations found in standard IVF, it is a rapid treatment and enables a quick progression into oncology treatment, whilst enabling fertility preservation. Furthermore the laboratory process of IVM can be employed when a young woman undergoes oophorectomy for malignancy, ideally after a few days of follicular stimulating hormone (FSH); whereby immature oocytes can be retrieved in the laboratory enabling IVM and oocyte cryopreservation (Walls et al., 2015a).

Stimulation Protocols

Various approaches to the process of IVM stimulation protocols have been employed and documented and extensively debated in the literature (Dahan et al., 2016). Protocols differ with respect to the need for ovarian stimulation with FSH prior to oocyte retrieval; to ensure a cohort of follicles starts to develop until the lead follicle is 10–12 mm in diameter at the time of follicular aspiration, versus the “natural cycle” approach where follicular aspiration is performed without the use of any stimulation. Furthermore, there exists further debate as to the requirement to administer to the patient a “trigger” injection prior to follicular aspiration. Whilst the use of the trigger is vigorously debated (Dahan et al., 2016), the only randomized controlled trial of the use of vs not use of a trigger injection did not demonstrate any significant differences in embryological or clinical outcomes (Zheng et al., 2012). Our protocol is to commence ovarian stimulation with a few days of 150iu of FSH, aspirate of follicles at a maximum diameter of 12 mm, without the use of a trigger injection, using a double lumen needle, and the maturation of the oocytes in the laboratory. In a subsequent frozen embryo transfer cycle, a single blastocyst will be transferred, and has led to clinical pregnancy rates that are the same as those in a standard IVF cycle (Walls et al., 2015b).

Laboratory Procedures

Oocyte Collection and Maturation

Oocyte collection for IVM is a modified version of a standard egg collection procedure; however, clinicians need to be specially trained to puncture follicles of a much smaller size. Both double and single lumen needles can be used and the follicles may be solely aspirated and/or the follicles can be flushed to maximize oocyte yield (Walls et al., 2015a). Flushing solutions can comprise

Fig. 1 An immature germinal vesicle oocyte (GV).

of buffered cell culture media (such as Hepes), Hartmann's supplemented with heparin or commercially available, specialized flushing solutions. Aspiration pressure has been reported from 7 kpa (52.5 mmHg) to 200 mmHg. Immature germinal vesicle oocytes (GVs) can be identified by sight, by specially trained embryologists (Junk and Yeap, 2012) or the aspirates can be filtered through a mesh strainer. Due to their very small size and lack of cumulus oophorus, oocyte identification is more difficult in an IVM collection procedure compared to a standard IVF TVOA. Removal of the GV stage oocyte from the follicle leads to a decrease in gap junction communication between the coronal cells and the oocyte. In turn, this results in and a dramatic decrease in cyclic adenosine monophosphate (cAMP) activity and the potential for spontaneous progression to the metaphase II (MII) stage. Spontaneous maturation can be problematic as nuclear maturation does not necessarily reflect cytoplasmic maturation, resulting in asynchrony between these two crucial events. This can effect downstream progression, including successful fertilization and ongoing embryo development (Figs. 1 and 2).

As with standard embryo culture, a range of media have been employed for IVM maturation culture. There are currently two commercially available IVM media, Sage (Cooper Surgical, USA) and Medicult (Origio, Denmark) and blastocyst culture media has also been reported with high success rates (Junk and Yeap, 2012). Regardless of the base media composition, hormonal additives recombinant luteinizing hormone (LH) and human chorionic gonadotrophin (hCG) are currently an essential part of maturation culture. FSH and LH mediate oocyte maturation by acting on granulosa cell receptors to induce the intracellular rise in cAMP activity within the oocyte and the subsequent cAMP cascade promotes the resumption of meiosis and germinal vesicle breakdown. Reported LH concentrations range from 0.1 IU/mL to 0.75 IU/mL and FSH from 0.075 IU/mL or 0.1 IU/mL.

Culture media additives

Other media additives including epidermal growth factor (EGF) and insulin like growth factor (IGF-I), (Gomez et al., 1993), activin (Alak et al., 1998), and meiosis activating sterols (MAS) (Smits et al., 2007) have been reported with varying success and are rarely used in routine IVM culture.

Fig. 2 In standard IVF—the oocyte is more readily identified than the oocyte in Fig. 1.

Fig. 3 Mature oocyte with expansion of the corona radiate.

Protein source in culture

Protein additives for IVM culture media include human follicular fluid (HFF) in concentrations ranging from 30% to 70% or more commonly, heat inactivated patient serum (maternal serum), ranging in concentrations from 10% to 20%. There have been reports of the use of fetal bovine serum (FBS) as concentrations of 10% or 20%; however, this is not advisable due to obvious ethical implications. The use of each of these additives carries with it the risk (however remote) of contributing contaminants to the embryo culture system and unknown concentrations of both positive and negative elements, which do not undergo rigorous quality assurance testing, unlike commercially available supplements and media.

Culture Timing

Following collection and transport to the laboratory, immature oocytes are cultured for timeframes between 24 and 40 h. Additionally, if a hCG trigger is used, culture times may vary to allow for insemination of oocytes according to the stages at which timing at which they are deemed mature. Following the designated period of maturation culture, oocytes should display expansion of the corona radiata (Fig. 3).

Fertilization and Embryo Culture

Fertilization in IVM has traditionally been performed using ICSI to overcome the potential for zona pellucida hardening. This is thought to be due to extended time in maturation culture and subsequently, lower fertilization rates occur; however, there is also evidence from a small sibling oocyte study suggesting fertilization rates to be comparable following a short 24 h maturation protocol (Walls et al., 2012).

Embryo culture following normal fertilization should not differ to that of standard IVF and continue according to the treating clinic's embryo culture protocol. Most IVM protocols employ cleavage stage culture and transfer/freezing; however, high rates of success have more recently been reported following day five to six, blastocyst culture (Junk and Yeap, 2012). There is some evidence to suggest that IVM derived embryos have a higher rate of early embryo arrest (Roesner et al., 2017) and therefore, blastocyst culture would allow for the selection of the most appropriate embryo for transfer and/or freezing for use in a frozen cycle.

Transfer and Cryopreservation

A freeze all approach is recommended in IVM protocols as implantation and live birth rates are significantly improved following frozen embryo transfers, as well as significantly lower rates of early miscarriage (Walls et al., 2015b). However, in fresh transfer cycles, endometrial priming with at least 6 days of estrogen initiated 2 days prior to TVOA and progesterone supplementation from the day of TVOA until the pregnancy test date, can also achieve high rates of implantation and ongoing pregnancy (Junk and Yeap, 2012).

Success Rates

Clinical pregnancy and live birth rates vary significantly between clinics and in the literature. Results are often difficult to compare due to variations in clinical protocols; however, using a freeze-all approach for IVM cycles implantation and live birth rates similar to standard IVF can be achieved, with similar long term outcomes for the children born (Shu-Chi et al., 2006).

Future Directions

The identification of oocyte secreted factors GDF9 and BMP-15 is an emerging area of IVM research (Mottershead et al., 2012) as well as cAMP modulators cilostamide and forskolin, as well as 3-isobutyl-1-methylxanthine (IBMX) which has shown to have no adverse implications for embryo chromosomal aneuploidy rates (Spits et al., 2015). Further large-scale trials into its effect on

human IVM success rates are required. Continued research into these factors may prove to be beneficial for IVM, should they prove to be successful culture media additives.

Conclusion

Several methodologies have been implemented in recent years to reduce the risk of OHSS; these include the administration of metformin, employing antagonist protocols and dopamine agonists (Cabergoline). Regardless, IVM is a safer alternative to traditional IVF, especially in a PCOS patient population due the complete elimination of the risk of OHSS. Additionally, IVM has the potential to treat a broader patient base including for fertility preservation and FSH resistant ovaries. While the research reporting on neonatal outcomes and developmental indicators have been positive (Shu-Chi et al., 2006), there is still a clear need for more research into the long-term outcomes for children born following IVM as well as large scale, multicentre, randomized control trials to more appropriately address the success rates of IVM compared to standard IVF treatment. Until that time, IVM should remain classified as an experimental treatment option.

Analysis of Fertilization

Introduction

Fertilization in general can be described as the event where the reproductive human cells; the haploid spermatozoa fuses with the fully grown and mature oocyte at the metaphase II stage of development to form a new entity which is the embryo. Sperm–oocyte interaction in vivo begins with the transport of spermatozoa through the female reproductive tract, many acrosome-intact spermatozoa reaching the mature oocyte within an hour. Only selected group of spermatozoa are capable of successfully penetrating oocytes and they need to undergo certain modifications in the female genital tract such as; capacitation, hyperactivation, and acrosome reaction. The last step acrosome reaction begins at the time of spermatozoa binding to the zona pellucida of the oocyte which may be induced in vivo by cumulus cells and follicular fluid. Fusion then occurs between sperm plasma membrane in the region of the equatorial segment and the oolemma. The spermatozoa becomes immotile at this point as it's incorporated into the oocyte, and all of the spermatozoon, including the sperm tail is fused into the ooplasm. Fertilization is completed with the sequential steps as; the activation of the oocyte with membrane fusions, exocytosis of the cortical granules to form the block to polysperm and prevent further sperm entry, and the activation of the metaphase II leading to the formation of the second polar body and the appearance of pronuclei with the complement of cytoplasmic syngamy, and nuclear syngamy events whereby the genomes of both gametes are merged to form a new embryonic genome, forming the zygote (Kupker et al., 1998).

Even though the analysis of normal and abnormal fertilization is inaccessible in natural conception cycles, the capability of observation of particular events by in vitro fertilization from the time of fusion until the complement of embryo development provides valuable information that would relate with healthy ongoing pregnancy and offspring. As abnormal fertilization in in vitro applications can give rise to nonviable embryos, the non-invasive assessments of zygote and embryos can be clinically relevant in routine practice of assisted reproduction techniques.

Fertilization Process by Assisted Reproduction

Conventional IVF (In Vitro Fertilization)

As the natural barriers of spermatozoon to penetrate through the cervical mucus and follow the genital tract to reach the oocyte is bypassed by in vitro fertilization less concentration of motile spermatozoa is needed for fertilization. Despite this necessity the semen samples are still treated with special preparation techniques, to select the most progressive spermatozoa, and to eliminate the spermatozoa with functional disorders.

ICSI (Intra-Cytoplasmic Sperm Injection)

Single spermatozoa mainly selected by morphological appearance is micro-injected into the cytoplasm of the mature oocyte at metaphase II stage for the ICSI procedure thus the essential steps for spermatozoa to bypass for successful fertilization such as progressive movement, integrity of sperm functions for zona pellucida and oolemma penetration and fusion with oolemma remains less important. As the barriers of natural selection of healthy, viable, and chromosomally normal spermatozoa are bypassed by the direct injection of spermatozoa within the oocyte, the selection of the single spermatozoon plays a critical role for ICSI cycles (Sakkas, 2013).

Contribution of the Oocyte Characteristics on Fertilization and Further Embryo Development In Vitro

Assessment of human metaphase II mature oocytes in in vitro fertilization is mainly performed by the examination of the morphological characteristics. Despite the fact that the morphology of oocytes is difficult to evaluate in IVF cases as the cumulus corona cells surrounding the oocyte would eliminate precise examination, ICSI procedures allow the assessment of various morphological variations of metaphase II oocytes that could correlate with its fertilization capacity, embryo quality and development as well as the clinical and neonatal outcome. Optimal oocyte morphology is defined as an oocyte with spherical structure enclosed by a uniform zona pellucida, with a uniform translucent cytoplasm free of inclusions and a size-appropriate polar body (Alpha Scientists in Reproductive Medicine and ESHRE Special Interest Group of Embryology, 2011). However Metaphase II-stage (MII) oocytes retrieved from patients after ovarian stimulation are known to show significant morphological variations that may affect the developmental competence and implantation potential of the derived embryo. Morphological abnormalities of the oocyte can be observed under two different subgroups; extracytoplasmic abnormalities and cytoplasmic abnormalities (Balaban and Urman, 2006; Balaban and Ebner, 2014).

Cytoplasmic abnormalities of MII oocytes include, different types and degrees of cytoplasmic granulations (slightly diffused or excessive whole/centrally located granulation) and appearance of refractile bodies, smooth endoplasmic reticulum clusters (sERCs), or vacuolization in the ooplasm. (Figs. 1A, B and 2A, B).

Despite the fact that the various degrees of diffused granulation in the cytoplasm does not seem to affect the fertilization capacity, embryo development and pregnancy outcome, condensed granulation that is centrally located within the cytoplasm with a clear border might have detrimental effect on the fertilization rates, embryo quality and more importantly chromosomal normality. Decreased pregnancy rates with such embryos, as well as increased abortion rates, are reported (Fig. 3A and B).

Fluid filled large vacuoles within the cytoplasm have a significant detrimental effect on the fertilization capacity of the oocyte, with a cut-off value suggested $> 14 \mu\text{m}$ in diameter. Large vacuoles are assumed to negatively affect a large proportion of the cytoskeleton (e.g., microtubules) which cannot function as it's supposed to. In addition to the detrimental affect on fertilization rates, large vacuoles can also negatively affect the embryo quality, blastocyst formation as well as the euploidy rates of the embryos obtained (Fig. 4A and B).

Presence of translucent vacuole like structures called as smooth endoplasmic reticulum clusters (sERC) are known to negatively affect the neonatal safety of the offspring and thus their utilization for fertilization in vitro is a continuous debate (Figs. 5A, B and 6A, B).

A variety of extracytoplasmic anomalies exist which in part negatively influence fertilization (consistency and thickness of the zona, polar body (Pb)1 decay and debris within the perivitelline space (PVS), blastulation (thickness of zona, Pb1 fragmentation), and pregnancy (thickness of zona, Pb1 morphology, debris in PVS). Characteristics of the zona pellucida and the PVS are most

probably associated with the health of the developing follicle, for example, its vascularization and oxygen content. Any disturbance during growth might severely alter oocyte morphology resulting in a pool of gametes with different prognoses (**Fig. 7A and B**).

Contribution of the Spermatozoon Characteristics on Fertilization and Further Embryo Development In Vitro

The effect of the spermatozoon, paternal genome on fertilization rates, embryo quality and especially the clinical outcome is less evident. All the natural barriers healthy spermatozoon with high fertilization capacity have to successfully achieve are bypassed and ignored during the ICSI procedure, for which a single spermatozoon is manually selected and inserted in the cytoplasm of the mature metaphase II oocyte. As the ICSI procedure is mainly applied for male factor infertility cases where poorer-quality spermatozoa is achieved, determination of defects that may adversely impact not only the fertilization, embryo viability and implantation potential but also the fetal outcome is of critical importance. Recent studies had shown that for the risk of neonatal and obstetric outcomes as well as congenital malformation rates for children born after the ICSI procedure for male factor infertility with ejaculated spermatozoon is not statistically different when compared with IVF treatments ([Belva et al., 2011](#)). For severe male factor infertility when epididymal or testicular spermatozoon is used overall neonatal health in terms of birth parameters, major anomalies and chromosomal aberrations of children born still seems reassuring in comparison to the outcome of children born after the use of ejaculated sperm ([Fedder et al., 2013](#)). More recent publications had also shown that ICSI with epididymal or testicular spermatozoon does not lead to more stillbirths or congenital malformations compared with ICSI using ejaculated

spermatozoon, and that the procedure is equally safe as even conventional IVF treatment (Guo et al., 2013). Despite this promising evidence, the seek for the selection of the ideal normal spermatozoa that would guarantee fertilization, good quality embryo and viable blastocyst development, and hence successful clinical outcome with the delivery of the healthy offspring, is still being investigated by novel technologies applicable in addition to classical morphological evaluation or as a solely method of selection with the aim of eliminating the utilization of spermatozoon with genetic integrity problems and DNA damage (Alpha Scientists in Reproductive Medicine and ESHRE Special Interest Group of Embryology, 2011).

Fertilization Abnormalities by IVF

Abnormal fertilization by conventional in vitro fertilization is mainly associated with abnormal polyspermy, due to the dispermic oocyte penetration resulting in trippronuclear (3PN) oocytes. Reasons for the appearance of 3PN include; uncontrollable multiple sperm penetrations, fertilization by a diploid sperm or oocyte, inhibition of second polar body extrusion and formation of two female pronuclei (or possibly one diploid) together with a single sperm pronucleus (monospermic dignity). The identification and elimination of polyspermic oocytes are critical as it's known that significantly higher spontaneous abortions are expected from the transfer of embryos derived from triploid zygotes. In addition to the dispermia and digyny the origin of trippronuclear zygotes may also be connected with their chromosomal constitution. New micromanipulation techniques such as microsurgical removal of a single pronucleus may provide an opportunity to repair the abnormalities of trippronuclear zygotes, especially for patients with high rate of hyperploidy (Ivakhnenko et al., 2000). Recent study by Escriba et al. (2006) demonstrating heteroparental blastocyst production from microsurgically corrected trippronucleated human embryos from conventional IVF had also been a hope for future studies of correction micromanipulations for hyperploidy embryos.

Another frequently seen abnormal fertilization type in human oocytes after IVF procedure is the visualization of a single pronucleus at the time of assessment of fertilization, instead of distinct two pronuclei as a sign of both female and male gametes. Despite the fact that earlier studies had shown high diploidy rate for embryos derived from single pronucleus after standard IVF, with 50% of the blastomeres having Y chromosome and healthy deliveries reported after the transfer of embryos derived with mononucleated zygotes (assuming that the second pronucleus can be observed at a later reassessment), or the fusion of the two pronuclei might appear at static observations by a certain time period, recent molecular cytogenetic studies of human single pronucleate oocytes suggest a significantly lower rate of diploid embryos, hence it is not recommended to use such zygotes in assisted reproduction purposes (Andrea et al., 2000).

Fertilization Abnormalities by ICSI

As only one spermatozoa is injected within a mature oocyte in the ICSI procedure, the formation of the third pronucleus appears as a result of decondensation of the unextruded polar body. The failure of the second polar body extrusion might be connected to; damage to the metaphase plate region during ICSI, reorientation of the first meiotic spindle or damage to the oocyte cytoskeleton during sperm injection, and misorientation of the second meiotic spindle, high estradiol (E2) levels on the day of hCG administration, and origin of spermatozoa; utilization of testicular spermatozoon or spermatozoon from severe oligoasthenoteratozoospermic patients. Typically it is recommended to eliminate embryos derived from trippronuclear zygotes formed after ICSI as high rates of spontaneous abortions and mosaic embryos are reported.

A recent publication in which 10 relevant studies for the removal of the third pronucleus were reviewed, reported the transfer of corrected embryos attempted only for once and resulted in live birth. This study indicated that obstacles associated with the procedure such as the identification of the supernumerary pronucleus, the presence of two centrosomes in dispermic oocytes, and cytogenetically abnormal patterns after intracytoplasmic sperm injection are still to be clarified, possibly offering patients with exclusively abnormally or few normally fertilized oocytes to benefit from epronucleation to guarantee embryo transfer or increase the number of embryos that could be transferred (Rosenbusch, 2009).

The percentage of haploid embryos obtained from mononucleated zygotes after ICSI are reported to be higher and varying percentages from 10% to 30% of embryos had been shown to contain Y chromosome. It has been suggested that monopronucleated ICSI zygotes may usually be parthenogenetically activated and not fertilized. Mateo et al., in contrast reported that even though the majority of monopronuclear zygotes after ICSI result from fertilization, as all embryos obtained were chromosomally abnormal, a significantly low percentage of embryos developed to good quality blastocysts, suggesting the deselection of embryos derived from monopronuclear zygotes (Mateo et al., 2013). Some similar studies also revealed that after the analysis of chromosome status of ICSI embryos derived from monopronucleated zygotes, that the diploidy rate is low and thus such embryos should not be used in assisted reproduction treatments.

Examination of Pronuclear Morphology and It's Predictive Value for Clinical Outcome

One of the mostly cited and frequently used scoring schemes to assess the quality and viability of embryos to be transferred by looking to the pronuclear morphology of normally fertilized zygotes with two distinct pronucleus clarified in the oocyte cytoplasm

Fig. 8 Schematic presentation of pronuclear morphology corresponding to individual patterns. Pattern 0 corresponds to normal zygotes whereas all the others are asymmetrical scores (Tesarik and Greco, 1999).

was published by Tesarik and Greco (1999). The morphological parameters evaluated included number of nucleolar precursor bodies (NPB) and their distribution in each pronucleus defined as polarized or non-polarized. The distribution of NPB was considered polarized when all NPB present in a pronucleus were present in the pronuclear hemisphere whose pole was the point of contact with the other pronucleus it was considered non-polarized when at least one NPB was found in the opposite hemisphere. The relative size of both pronuclei (equal or unequal) and their position with regard to one another (in apposition versus at distance) were also noted. Five patterns based on these parameters were defined in the pronuclear grading scheme of Tesarik and Greco (Fig. 8).

The developmental fate analysis of zygotes with different patterns of pronuclear stage morphology had shown that these patterns can significantly predict the percentage of arrested embryos, embryos with multi-nucleated blastomeres (MNB), and good quality embryos. Pattern 0 which were zygotes giving rise to embryos transferred in 100% implantation cycles were defined as the ideal zygotes with; the number of NPB not showing big differences between both pronuclei, never differing by more than three, NPB being always polarized when they were fewer than seven and never polarized when they were more than seven in a pronucleus, the number of NPB in a pronucleus never fewer than three, and the distribution of NPB being either polarized or non-polarized in both pronuclei, but never polarized in one pronucleus and non-polarized in the other. All other patterns were defined as asymmetrically developing zygotes. Embryos originated from pattern 0 zygotes had significantly less percentage of arrested embryos, embryos with multi-nucleated blastomeres (MNB), significantly higher number of good quality embryos when compared with all other pattern groups. In a follow-up study they examined the clinical validation of their grading scheme and found in 380 fresh embryo transfer cycles that the clinical pregnancy and implantation rates were significantly higher for the group of patients who received embryos originated from pattern 0 zygotes, and that the transfer of only one pattern 0 embryo was sufficient for the optimal chance of pregnancy whereas transfer of two pattern 0 embryos mostly resulted in twin pregnancy (Tesarik et al., 2000). Balaban et al. (2001) also demonstrated that embryos showing an ideal pronuclear pattern 0 cleaved earlier and faster and resulted in better quality cleavage stage embryos and blastocysts. The incidence of blastocyst formation was very high; 72% in zygotes showing a 0 pattern, compared with 12.7% in zygotes with double abnormalities assessed by Tesarik and Greco grading scheme. In addition to better embryo quality and blastocyst formation, higher implantation and pregnancy rates were obtained when at least one blastocyst derived from a 0 pattern zygote was included in the set of embryos transferred. A more recent joint study by Balaban et al. (2004) also showed that both embryo cleavage characteristics (such as cleavage rate, embryo quality and blastocyst formation) and chromosome constitution of the embryo were related with pronuclear morphology. Embryos developing from zygotes with the normal PN pattern 0 cleaved faster and formed embryos with better morphology as compared with zygotes with abnormal pronuclear patterns. Aneuploidy rate of embryos derived from zygotes with the normal pronuclear pattern was significantly lower when compared with embryos derived from single or double pronuclear abnormality. Chromosomally normal embryos with the normal pattern 0 progressed to the blastocyst stage at a significantly higher rate than chromosomally normal embryos with single or double pronuclear abnormality. The same relationship applied to chromosomally abnormal embryos.

An alternative grading scheme that had also been widely cited and utilized is the one published by Scott and Smith (1998) which is based on empirical observations correlated with pregnancy. The basis of this grading scheme was a combination of pronuclear

size, nucleoli number and distribution, and cytoplasmic appearance that prospectively showed an increase on the incidence of implantation when utilized for day one embryo transfers and to select embryos for cryopreservation. As a continuum of this study, [Scott et al. \(2000\)](#) published a revised pronuclear grading scheme with the aim of better predictivity and easy and fast use for laboratory staff. The new grading scheme examined the cleavage stage and blastocyst stage embryo characteristics as well as their implantation potential in correlation with zygote morphology. The revised grading system was named as Z scoring scheme at which the zygotes were scored from Z1 to Z4, Z1, and Z2 representing the ideal zygotes that would give rise to implanting embryos. Similar to the previous scheme, the grading took into account the nuclear size and alignment, nucleoli number and distribution. The nucleoli needed to be aligned, or be beginning to align, at the pronuclear junction, between three and seven per nucleus with no more than one nucleolus difference between the nuclei and equal in size. Although the size of the nucleoli was not measured, zygotes with either very small pinpoint nucleoli or very large ones were designated as Z3. The study had shown that embryos derived from Z1 and Z2 scored zygotes have an higher rate of blastocyst formation. The pregnancy and implantation of embryos derived from Z1 and Z2 scored zygotes were also significantly higher ([Fig. 9](#)).

As in connection with the earlier hypothesis indicating that nucleolar patterns are closely linked to embryo viability, thereby reinforcing the relevance of polarity in human oocytes and embryos, it appears that pronuclear scoring can successfully be incorporated into the practice of embryo evaluation for prediction of implantation potential, and embryo normality of the individual embryo ([Balaban and Urman, 2003](#)). A recent systematic review on forty studies examining the effectiveness of zygote morphology evaluation in fresh IVF and ICSI cycles revealed that the majority of the evidence based clinical trials supported the utilization of the grading schemes by Tesarik and Greco, or Scott Z scoring system with minor modifications ([Nicoli et al., 2013](#)). This review also demonstrated that zygote morphology correlated significantly with embryo quality and cleavage, blastocyst stage, embryonic chromosome status, in a high proportion of the studies which assessed the specific outcome.

Timing of assessment of pronuclear scoring is of major importance as the pronuclear formation is a dynamic event that would eventually disappear by the beginning of the cleavage events of the embryos. The systematic review had shown that various timings differing from 14th to 18th hour post-insemination was being used in clinical trials for IVF and/or ICSI cases. Taking into the consideration the dynamic development of a human embryo, the heterogeneous results reported might be correlated to these timing differences of examination of pronuclear sizes, as well as polarization dynamics of the NPBs. In the time course leading to the initiation of pronuclear formation, zygotes arising from IVF are observed to be approximately an hour behind those arising from ICSI, and thus the widely used and recommended timing based on earlier studies for 16th–18th hour of assessment may not be appropriate time not only for the observation of visualization of normal fertilization with two distinct pronuclei and two polar bodies but also for the examination of pronuclear morphology. The Istanbul consensus workshop proceedings published by Alpha Scientists in Reproductive Medicine and ESHRE Special Interest Group of Embryology suggested that the fertilization as well as pronuclear morphological characteristics of a zygote should be assessed at 17th with minus or plus an hour maximum flexibility ([Alpha Scientists in Reproductive Medicine and ESHRE Special Interest Group of Embryology, 2011](#)). A simplified consensus grading scheme for pronuclear scoring was also suggested in the consensus paper. According to this grading system three categories were defined by which category 1 represented symmetrical zygotes that are equivalent to Z1 and Z2 as referred by Scott and Smith, category 2 represented non-symmetrical zygotes with all other arrangements of pronuclear appearances, and category 3 represented abnormal zygotes with 0 or 1 NPB within the pronuclei ([Figs. 10A, B and 11A, B](#)).

Fig. 9 Diagrammatic representation of Z-scoring by [Scott et al. \(2000\)](#). Z1 and Z2 represents normal zygotes whereas all the other arrangements are considered asymmetrical.

Consensus scoring system for pronuclei		
Category	Rating	Description
1	Symmetrical	Equivalent to Z1 and Z2
2	Non-symmetrical	Other arrangements, including peripherally sited pronuclei
3	Abnormal	Pronuclei with 0 or 1 NPB

Fig. 11 (A and B) Category 1 pronuclear score—according to alpha and eshre special interest group of embryology consensus grading scheme (2011).

Dynamics of Fertilization, Pronuclear Development and Morphology

One of the major drawbacks of morphological evaluations and grading schemes of embryos, starting from the zygote level to the blastocyst stage, is that the assessment is performed at static developmental time points by microscopy. As the human embryo is a highly dynamic and complex entity the static evaluation of such a cell will always have limitations for viability and implantation competency assessments, by missing some of the important cleavage events that could be visualized by continuous monitorization. Time-lapse incubation systems have let the predictive value and objectivity of morphological grading schemes to be revisited, and open a debate for the necessity of revised scoring systems emphasizing the need for a new look on embryological parameters.

The study Montag et al. (2011) analyzed pronuclear morphology based on time-lapse imaging for the distribution of NPB at 14–15th, 16–18th, and 19–20th hours and found out that 14–15 h to 16–18 h similar pronucleus scorings were present in 75% zygotes, whereas 25% showed change in the patten which resulted in another pronuclear score. The change in the pronuclear score from 16–18 h to 19–21 h was 33.8%, whereas 66.2% remained in the similar pronuclear scores. The documented changes were mostly from an asymmetric distribution of NPB towards a symmetric or perfectly aligned distribution. The change from a symmetric to an asymmetric pattern was less common. These dynamic changes reported in the study can perhaps explain the contradictory situation in the literature where static observations for zygote morphology were reported. The prospective study by Azzarello et al. (2012) was performed on 159 embryos, all of which were transferred. The pronuclear morphology of the 46 embryos which resulted in live birth was compared with that of 113 embryos which resulted in no live birth. Pronuclear morphological assessment was performed on day of embryo transfer, using six different scoring systems at different times. The study showed that no embryo with pronuclear breakdown earlier than 2 h 45 min resulted in live birth, all six pronuclear assessment models showed no significant distribution of scores between the live birth and no live birth groups at the 16th and 18th hour post-fertilization and 40 min before pronuclear breakdown. The outcomes of assessments changed significantly over time and the time of pronuclear breakdown was found to be the optimal stage to evaluate pronuclear morphology. In agreement with published Works, this study also demonstrated that pronuclear morphology changes over time, showing that the single static observation is deficient in comparison to dynamic continuous observation. Even though the examination of the pronuclear morphology did not improve the embryo selection, the timing of pronuclear breakdown was suggested to be a more objective criteria for prediction of live birth. The study by Aguilar et al. (2014) compared the timings of early fertilization events by time-lapse imaging which were the second polar body extrusion,

first and second pronuclei appearance, pronuclear syngamy so called as abuttal, pronuclear movements within the cytoplasm, pronuclear morphology, pronuclear symmetry, pronuclear fading and the length of S-phase which is defined as the time from pronuclear appearance to pronuclear fading in implanted versus nonimplanted embryos in a 2 year cohort study. The timings at which second polar body extrusion (3.3–10.6 h), pronuclear fading (22–25.9 h) and length of S-phase (5.7–13.8) occurred were linked successfully to embryo implantation, and all the other parameters defined were unrelated with embryo implantation competency.

All these studies on the continuous observation of early fertilization events offer a new era to revisit the changes in fertilization phenomenon and the necessity of a more close examination of the dynamism of pronuclear morphological changes.

Conclusion

Successful fertilization process is a complex and highly dynamic biological phenomenon that includes several events which are closely correlated with the developmental capability and viability of the resulting embryo. The events in summary are the exclusion of the second polar body, the appearance and fading of the pronuclei, and the pronuclear syngamy which all happen before or after the conventional first embryo observation performed at 16–22 h. post insemination., most likely remaining unidentified when the assessment is performed at fixed time points (Balaban et al., 2017). Continuous observation of embryo development by time-lapse technology will not only provide valuable information for cleavage or blastocyst stage characteristics of the embryo but also may detect some critical abnormalities that start at the very early stage of the fertilization process. Despite the fact that the majority of clinical time-lapse studies identify information on the cleaved embryo, more future trials will guide us through the details of the human first cell cycle which may introduce alternative objective parameters for the selection of embryos with higher implantation probabilities that would lead us to successful clinical outcome.

Introduction

One of the successes of assisted reproduction techniques, it focuses on maintain optimal embryo viability, thus, an essential step during assisted reproduction treatments, is to keep the best in-vitro culture conditions of embryos and the optimization of this conditions, in order to select those with the highest developmental competence.

Two kinds of protocols, regarding culture media, are widely used in assisted reproduction laboratories. (A) Simple protocols, containing essential media for early embryo development; they are used for embryo culture from zygote to day 3 (Ertzeid et al., 1999; Shahine et al., 2011; Biggers and Summers, 2008); and (B) sequential protocols, to complete the development until blastocyst stage, providing more complex energy pathways required for these stage of development. Sequential culture can be made changing the medium to another with a different composition according embryo's requirements; or without change the medium composition, using a single step media with refreshment on day 3, or single step media without any refreshment for uninterrupted culture (Biggers and Summers, 2008; Balaban and Urman, 2005; Gardner, 2008; Hambiliki et al., 2011; Swain et al., 2016).

Continuous embryo culture in single-step media could have several important advantages, for example, offer the benefit of cost and simplified laboratory management, decreased embryonic stress, reduced pH and temperature fluctuations, compatibility with ever more popular time-lapse imaging culture systems (Costa-Borges et al., 2016; Sfountouris et al., 2017). However, culture conditions vary from lab to lab.

It is widely recognized that on assisted reproductive technology laboratories, in addition to the culture media, other components and conditions like gas phase, pH, culture vessel, incubation chamber, laboratory air quality, the training of embryologists and patient-own clinical characteristics, are very important, and its dynamic interaction with the culture system it is essential to provide a stable environment for embryos development (Swain et al., 2016; Swain, 2012, 2015). To this date, many different culture systems are development to improve the "in vitro" conditions, trying to mimic the physiologic environment that embryos have in the female reproductive tract. Thus, different platforms and systems have been developing to carry out an optimal culture of the human embryos. Table 1, summarize almost all culture systems that have been developed. Describe the most used, as well as the most recent and novel ones, is the objective of this article.

Microdrop Culture System

Conventional, flat sterile Petri dishes are the most common and traditional platform for embryo culture. Microdrops embryo culture, is one of the static system historically used by many assisted reproduction laboratories worldwide (Reed, 2012). The embryos are cultured in microdrops of variable volumes of medium, depending of the lab (10–50 µL) in Petri dishes, which are mostly covered with mineral oil to restrict evaporation. Then, dishes are placed into a standard incubator on controlled CO₂ and temperature conditions.

Physical culture environment, seems results important and may influence on embryo development. The way of embryo culture inside the drop (individually or by groups), could affect chemical environment because varying embryo spacing, being able to modify its development. Many efforts have been made to improve culture media and maintain the optimal microenvironment. However, most of these studies are made on animal models (Swain and Smith, 2011).

Table 1 Culture platforms

Statics	Ultra-microdrops
	Microdrops
	Submicroliter platforms
	Microwells

	Microfluids
	Shaking or rotation
	Vibration
Specialized	Tilting
	Agarose
	Hyaluronic acid
	Coculture
	Matrigel
	3-Dimensional matrix

On another hand, this kind of culture system, require more embryo manipulation, because occurs by manual pipetting and multiple observations are expected to give a better understanding of embryo development. The evaluation is made by the embryologist under microscopy outside incubator, almost every day during the embryo development. It is recognized that each observation involves handling and exposure of the embryos to suboptimal conditions outside the controlled environment.

Coculture System

Further optimizing culture conditions, for example by using improved culture media and paying exhaustive attention to the laboratory conditions, some groups have experimented with different coculture systems in the opinion that feeder cells would provide some factors missing from artificial culture media that would improve embryo quality (Eyheremendy et al., 2010).

The suggested beneficial effect of coculture system seems to fall on the fact of create a more physiologic environment, since includes the secretion of embryotrophic factors that may influence positively on embryo development. Multiple cell types have been used for this purpose, creating a surface that housing the embryos during the culture (Barmat et al., 1998; Mercader et al., 2006). Most recently, autologous endometrial cell monolayer coculture has yielded promising results for improved human embryo in vitro development (Rubio et al., 2000; Dominguez et al., 2010). However, there are controversial opinions about enhanced rates of blastocyst formation, and improve on implantation rates when embryos were cultured on the cells, or above them, compare to traditional culture systems. Although it has been used extensively in the past, it is a less widely used culture system, probably due to the delicate anterior process that epithelial and stromal endometrial human cells must have during their isolate and growth (Swain and Smith, 2011; Mercader et al., 2006; Simon et al., 1999).

Microfluids

At the beginning, microfluidic systems appeared to miniaturize devices designed for chemistry analysis and some molecular biology procedures. This technology is an emerging field and more recently, are being used as cell culture platforms. Even, some studies show possibilities to use them as an alternative for conventional ART techniques like sperm isolation, oocyte denudation, in vitro fertilization and embryo culture. In studies of assisted reproduction, microfluidics has some advantages like the very low consumption of culture media, in addition that the fluid in microchannels can be precisely predicted and controlled, among others (Han et al., 2010).

It is known that microchannels provide an environment that seems to be advantageous for embryos since mimic the active fluid situation that take place in vivo, compare to traditional static microdrop embryo culture methods. Microfluidics cell culture devices permits a gradual change of the culture medium, which might result in better embryo development and also reduces embryo manipulation. Although microdrop culture allows autocrine factors retention around embryo, it does not provide mechanical stimulation, and not mimicking the natural way of embryo culture. In vivo, the embryo goes through the Fallopian tube and is thus bathed in a flux of fluid of different composition, and the medium around the embryo change continuously, waste products are removed and probably the embryo senses the flux of medium and mechanical stimulation (Swain and Smith, 2011).

Microfluidics devices may be a new approach to solve this problem and might replace conventional human embryo culture in microdrops in the future. Probably microfluidics could reduce handling and disturbance of optimal culture conditions along each ART process, providing the suitable medium at the correct time and place and at the right flow rate in multiple channels at the same time, and all in one device with a minimal handling. Currently, there are very few microfluidic platforms that integrate all the IVF culture process in human embryos. However, to achieve this goal, some research groups are testing prototypes.

Time-Lapse Technology

Standard embryos assessments are based on subjective morphology evaluation, often with inter and intra observer variability, which joined to the increased handling and higher evaluation frequency, will expose the embryo to negative changes on important parameters that may affect its development such as temperature, humidity and gas composition (Meseguer et al., 2012).

Time-lapse is considered a novel noninvasive system and an important tool on ART, based on conventional incubators incorporating an image capture system which take pictures of the embryos in several focal plans at defined time intervals. The fusion of all the frames of each embryo generates a recording that lets visualizing the entire embryo development, in order to determine the exact moment in which each event occurs, with a better objectivity and precision since inter and intra observer variations is reduced and allows to detect any abnormal events that would normally occur between observations. In this way, embryo evaluation is done without taking them outside the incubator to minimize its manipulation while are maintaining on stable embryo culture conditions (Aparicio et al., 2013; Basile et al., 2015a). In another way, the use of kinetic markers can improve embryo selection and with an appropriate algorithm, can improve clinical results and increase implantation rates (Meseguer et al., 2011; Rubio et al., 2014; Basile et al., 2015a, 2015b).

At this time, more time-lapse incubators are available and being in use, because they represent a noninvasive tool for improving embryo selection without disturbing culture conditions (Meseguer et al., 2011). Morphokinetic evaluation may yield an important information for better embryo selection (Costa-Borges et al., 2016; Meseguer et al., 2011; Herrero and Meseguer, 2013).

Table 2 Time-lapse systems features

	Embryo-Scope	Geri	Primo Vision	Eeva	Miri	Embryo-Scope+
System	Vitrolife	Genea Biomedex	Vitrolife	Merck-Serono	ESCO Medical	Vitrolife
Optics	Bright field	Bright field	Bright field	Dark field	Bright field	Bright field
Focal planes	7	12	1	1	1	7
Embryo imaging	Pictures every 10'	Pictures every 10'	Pictures every 10'	Pictures every 5'	Pictures every 5'	Pictures every 10'
Capacity	6/system	6/system	1/camera	1/camera	6/system	15/system

Integrated incubator	Yes—Hybrid	Yes—Benchtop	No	No	Yes—Benchtop	Yes—Hybrid
Data analyses	Manual	Manual	Manual	Real Time	Manual	Manual
Selection algorithm	User defined	User defined	User defined	Yes	User defined	User defined

There are different alternatives of time-lapse systems available in the market. From those with single fully integrated equipment, for example, EmbryoScope®, Geri and Miri® TL; to those that introduce a microscope inside an available incubator, for example, Primo Vision® and The Eeva™ Test. **Table 2**, describes some features of the time lapse systems available.

Final and Future Considerations

At this time, our vision of some culture systems is like a big puzzle with few connecting pieces; thinking which of them could be the better one to maintain the best conditions for embryos development, and finally may improve our clinical results. However, these pieces will gradually joined and we can imagine the future. Therefore, it is perfectly conceivable visualize in this future devices with video time-lapse systems and probably with microfluidics technology without continuous embryo manipulation, that can replace current IVF platforms. Henceforth, embryologist tasks will also change because continuous gamete/embryo handling and assessment will no longer be necessary. New tasks can be clinically managed in IVF labs, such as supervise this possible automated procedures, to improve their technology/scientific background and to conduct active research with the embryological data generated by these new devices.

Human Embryo Development and Assessment of Viability

Introduction

The preimplantation period of human embryo development is marked by several key morphological, physiological and genetic changes, all of which occur within a 6-day period, after which the embryo implants into the endometrium of the uterus. From fertilization in the oviduct, to implantation in the uterus, the embryo develops from a totipotent single cell, to a multicellular blastocyst of over 100 cells, which contains two distinct cell populations. The outer layer of the blastocyst, which subsequently forms the placenta is referred to as the trophoblast and represents the first transporting epithelium of the conceptus. Within the fluid cavity, the blastocoel, resides an eccentrically placed group of cells known as the inner cell mass, and it is from this smaller group of cells that the fetus develops. During this period of life the embryo is free floating within the female tract and derives all of its nutrients from the surrounding fluids. This environment is characterized by nutrient and oxygen gradients as the embryo passes through the oviduct and uterus (Gardner et al., 1996; Ng et al., 2017), and becomes increasingly more complex in composition with the uterine environment providing an array of cytokines and growth factors (Hannan et al., 2011).

Development of the human embryo in vitro was significantly improved when culture media started to reflect the composition of the female reproductive tract, rather than being empirically derived (Gardner and Lane, 1997, 2017). Now it is possible to maintain the human embryo through to the blastocyst stage in culture, resulting in improved outcome for patients undergoing in vitro Fertilization (IVF) procedures. Analysis of embryo morphology, kinetics of development and the analysis of metabolic function have all been linked, to some degree, to pregnancy outcome. The future of human IVF will see the development and application of further biomarkers of developmental potential, potentially combined with the introduction of microfluidic devices, which are suited to single embryo/cell analyses (Thouas et al., 2013).

The Environments Created by the Female Reproductive Tract to Support the First Week of Life

The environments created within the lumen of the female reproductive tract are designed to support the stage-specific needs of the developing embryo, and are not simple serum-transudates (Leese, 1988). Hence, fluids within the oviduct and uterus are unique, complex and change with regards to the day of the menstrual cycle. Human oviduct fluid is comprised of high levels of albumin and mucins, and contains pyruvate (0.32 mM) and lactate (10.5 mM) and low levels of glucose (0.5 mM) (Gardner et al., 1996). Mammalian oviduct fluid is characterized by very high levels of specific amino acids including alanine, glutamate, glycine and taurine (Harris et al., 2005; Miller and Schultz, 1987), and has oxygen levels of between 5% and 8% (Gardner and Lane, 2017; Ng et al., 2017). In contrast, uterine fluid is somewhat more complex, characterized by the presence of glycosaminoglycans, especially hyaluronan and a rich reservoir of growth factors and cytokines. Uterine fluid has relatively high levels of glucose (3.15 mM), and low levels of pyruvate (0.1 mM) and lactate (5.87 mM) (Gardner et al., 1996). The level of oxygen in the uterus ranges from ~2.5% to 5% and is considered to drop close to 2% around the time of implantation (Gardner and Lane, 2017; Ng et al., 2017). As well as providing gradients of nutrients to the embryo, which also act as signals to the embryo (Gardner and Harvey, 2015), the embryo is exposed to numerous cytokines and growth factors, whose levels not only change with the day of the menstrual cycle, but also differ between fertile and infertile patients (Hannan et al., 2011), thereby indicating they have important roles in regulating embryonic development, differentiation and implantation. Hence, the environment to which the human preimplantation embryo is exposed to in vivo is anything but constant. As the biology of the developing embryo is considered in detail, the significance of the dynamic environment created within the maternal tract becomes evident.

Biology of Human Preimplantation Development

The human oocyte is the largest cell in the female, being ~110 µm in diameter, and is surrounded by a glycoprotein coat known as the zona pellucida. The zona serves not only to prevent polyspermy postfertilization, but also prevent premature attachment and possible invasion of the developing embryo into the wall of the oviduct. The zona is subsequently lost at the blastocyst stage through the action of both embryo and uterine-derived proteases. After Fertilization, the embryo must undergo the extrusion of the second polar body, decondensation of the sperm head, pronuclei formation, and finally the breakdown of the pronuclear membrane. The fertilized oocyte is totipotent, in that it can give rise to every cell type in the body. In the human preimplantation embryo, the first few divisions are referred to as restrictive mitoses, in which the cells (known as blastomeres) divide but the daughter cells are smaller. This is required to restore the cytoplasmic: nuclear ratio, which is abnormally high in the fertilized oocyte. The first of these divisions occurs around 18 h after fertilization, with subsequent divisions occurring approximately every 12 h, although there is variation between embryos (Meseguer et al., 2011). Up to the 8-cell stage, individual blastomeres are held in proximity by the zona, but are not joined per se. Indeed, a breach in the zona could lead to a loss of cells. In terms of their physiology, individual blastomeres lack sophisticated means of regulating their homeostasis, such as pH control, and are therefore more dependent

upon the maternal tract to provide the appropriate environment (Gardner and Lane, 2005; Lane and Gardner, 2005). Between the 8- to 16-cell stages, the embryo undergoes a significant change, with the formation of the first transporting epithelium, achieved through the creation of tight junctions between adjacent cells. This facilitates not only a means to control the internal environment of the embryo, but also creates an inside and out, with cells developing on the inside of the embryo being destined to become the fetus, while those cells on the outside become allocated to extra-embryonic membranes such as the placenta (Fleming and Johnson, 1988). Down the microscope, the appearance of individual blastomeres is lost at the 8- to 16-cell stage as the cells flatten or compact against each other, forming not only tight junctions at the apical surface of the cells, but also forming gap junction between cells. This process is aptly referred to as compaction, and the embryo becomes known as the morula. At this stage the embryo resembles a mulberry, and it is from this that the name morula was derived. Rather than continuing to develop as a solid ball of cells, the outer cells of the morula start to create a cavity through the action of Na/K ATPases on their basolateral membranes, thereby creating an ionic gradient, inducing the formation of a fluid-filled cavity, known as the blastocoel (Kidder and Watson, 2005). The embryo is then referred to as the blastocyst. Cells that have been developing on the inside of the embryo develop into a distinct group known as the inner cell mass (ICM), while the outer cells become the trophoblast (TE). While the pluripotent ICM cells are destined to form the fetus, the trophoblast cells have the incredible task of invading into the maternal endometrium lining the uterus, establishing a blood supply, and preventing the mother from rejecting the nonself embryo. Fig. 1 shows the spatial positioning of the human preimplantation embryo as it develops within the lumen of the female reproductive tract, while the detailed characteristics of human embryo development are illustrated in Fig. 2.

The complex dialogue that exists between the blastocyst and endometrium is far from understood, but what we can deduce is that cancers employ the same biological strategies as the trophoblast to invade a host tissue and establish its own vasculature (Gardner, 1998a,b, 2015). Indeed, analysis of the implantation process has much to inform us about cancers.

Dynamics of Embryo Physiology From the Fertilized Oocyte to the Blastocyst

From Fertilization to the 4 to 8-cell stage the human embryo is dependent upon stable mRNAs and proteins synthesized during oocyte maturation. Around this time the embryonic genome begins to be transcribed, and between the morula and blastocyst stages

Fig. 1 Schematic of the human female reproductive tract and the relative position of the preimplantation embryos as it develops and differentiates. From fertilization in the ampulla of the oviduct, through to implantation in the endometrium 6–7 days later, the human embryo undergoes remarkable development and differentiation, all the while being exposed to an ever changing environment. The oviduct is characterized by relatively high levels of pyruvate and lactate and an oxygen concentration of around 8%. In contrast, uterine fluid is characterized by relatively high levels of glucose and lower concentration of oxygen. Further, the uterine environment is one containing numerous cytokines and growth factors.

Fig. 2 Key morphological features of embryos with high viability. ICM: inner cell mass, TE: trophectoderm. Gardner, D.K., Balaban, B. Assessment of human embryo development using morphological criteria in an era of time-lapse, algorithms and OMICS: Is looking good still important? *Molecular Human Reproduction* 22, 2016, 704–718 with permission.

there is a dramatic increase in embryonic gene expression, so that by the blastocyst stage the embryonic genome is active (Hamatani et al., 2006; Jukam et al., 2017). As the human embryo progresses through the preimplantation period, it undergoes changes in morphology, exhibits an exponential increase in cell number, and forms its blastocoel. Underlying all of this are remarkable changes in metabolism; the embryo changes the relative activity of specific pathways as a means of fulfilling the changing requirements as development proceeds. The metabolic transformation has typically been perceived as a means to an end with regards to developmental processes. However, it is now perceived that in some cases it is the metabolism of the embryo that regulates specific processes (Gardner, 2015; Gardner and Harvey, 2015), as will be elucidated.

The human oocyte is a truly remarkable cell given that it can reside in the ovary for up to 40 years and still give rise to a viable pregnancy. In order to achieve this, the oocyte exhibits a unique metabolism, one based primarily on low levels of oxidation of pyruvate, with little to no ability to utilize glucose. Oxygen consumption by the embryo remains low until after compaction (Kurosawa et al., 2016). The quiescent nature of the oocyte's existence means that its energy demands are extremely low. When a cell does not utilize energy, any ATP synthesized is not immediately used, and hence the cell is characterized by a high ATP:ADP ratio, and this is true of the oocyte (Leese et al., 1984). A direct consequence of this high ratio is the allosteric inhibition of a rate-limiting enzyme in glycolysis, phosphofructokinase (PFK), hence explaining why the oocyte cannot metabolize glucose. The fertilized oocyte shares the same metabolism as the unfertilized egg. Indeed, it is not until the 4- to 8-cell stage that the embryo can utilize glucose as an energy source. As the embryo commences its divisions, and cell number increases, there is a concomitant increase in the demand for energy, which is required not solely for cell proliferation, but also for the formation and maintenance of the blastocoel (the latter representing a constant energetic demand). Consequently, the absolute levels of ATP decline as it is rapidly utilized, resulting in a reduction in the ATP:ADP ratio, and a concomitant increase in AMP, both of which have a positive allosteric effect on PFK, and thereby facilitating a high flux of glucose through glycolysis. Oxygen consumption subsequently rises significantly upon formation of the blastocyst. However, rather than oxidizing all of the glucose consumed, the blastocyst exhibits an idiosyncratic trait referred to as aerobic glycolysis, where lactate is produced from glucose even when there is sufficient oxygen for its complete oxidation. This type of glucose metabolism was first described in cancers by Otto Warburg in 1923, and is hence referred to as the Warburg Effect. Warburg proposed that the high levels of lactate produced by tumors were a result of impaired mitochondrial function, however this does not appear to be the case. Certainly the mitochondria of the blastocyst have the capacity for oxidative metabolism. So what is the significance of this rather intriguing situation?

Although energetically unfavorable, aerobic glycolysis ensures that the biosynthetic arm of the pentose phosphate pathway (PPP) has maximum substrate availability at all times. As with all proliferating cells, there is a demand for biosynthetic precursor provision for membrane and nucleic acid synthesis. Glucose has a significant role in cellular biosynthesis, its carbon being required for the synthesis of triacylglycerols, phospholipids and as a precursor for complex sugars of mucopolysaccharides and glycoproteins. Hence, glucose is required by the morula and blastocysts stages not only for energy but to provide the intermediates for biosynthesis and the ribose moieties for RNA and DNA synthesis (Gardner, 1998a,b; Gardner and Wale, 2013). The complexities and dynamics of human embryo metabolism are highlighted in Fig. 3. Recently, the significance of aerobic glycolysis for the blastocyst implantation has been re-visited (Gardner, 2015). It is proposed that the human blastocyst has the capacity to create a microenvironment, characterized by high lactate and reduced pH, both of which facilitate the breakdown of the endometrial extracellular matrix, are involved in angiogenesis and actively help to modulate the local immune response to the blastocyst. It seems that embryonic metabolism is far more than energy production.

Human Embryo Culture

Given the dramatic differences in the physiology and metabolism of the embryo before and after compaction, optimizing the culture of the human preimplantation embryo has been challenging. However, through analysis of human female oviduct and uterine fluid, sequential media were developed, capable of supporting the human embryo throughout the preimplantation period (Gardner and Lane, 1997), leading to increased implantation rates (Gardner et al., 1998). Today, blastocyst transfer is considered the standard of care in human IVF. Of significance, oxygen is a powerful regulator of the preimplantation embryo, and hence whenever possible, human embryos should not be exposed to atmospheric oxygen (~20%), but rather cultured in the presence of more physiological levels, i.e., ~5%.

Analysis of Development and Viability: Morphology

What are the key morphological parameters during the cleavage stages that are associated with subsequent embryo viability and implantation potential post transfer? The percentage and localization of fragmentation, evenness of the blastomeres, multinucleation and rate of cleavage are features typically assessed to evaluate the quality of a cleavage stage embryo on day 2 and day 3 (Gardner and Balaban, 2016). The common characteristics of embryos with high viability include 4 or 5 blastomeres on day 2, and at least 7 blastomeres on day 3 after fertilization, with < 20% fragmentation and no signs of multinucleation. Rienzi et al. (2005) suggested a cumulative classification scheme based on the most essential morphological features that should be examined to evaluate a cleavage stage embryo. Morphological parameters selected were cleavage rate, blastomere symmetry, cytoplasmic appearance, extent of fragmentation and blastomere nucleus status. Such a grading scheme effectively predicted blastocyst formation and

Fig. 3 (A) *Metabolism of the pronucleate oocyte and cleavage stage embryo.* Prior to compaction the embryo has a metabolism based around low levels of oxidation of pyruvate, lactate and specific amino acids. The ovulated oocyte is surrounded by, and is directly connected to, cumulus cells which actively produce pyruvate and lactate from glucose. This creates a high concentration of pyruvate and lactate and a low concentration of glucose around the fertilized oocyte. Upon dispersal of the cumulus cells, the human zygote and cleavage stage embryo still find themselves in a relatively high concentration of pyruvate (0.32 mM) and lactate (10.5 mM), and low levels of glucose (0.5 mM) within the ampulla. The early embryo is characterized by a high ATP:ADP level, which in turn allosterically inhibits PFK, thereby limiting the flux of glucose through the glycolytic pathway prior to compaction. Significantly, the relative abundance of nutrients affects the metabolism of the embryo. For example, the ratio of pyruvate:lactate in the surrounding environment directly affects the ratio of NADH:NAD⁺ in the embryo, which in turn controls the redox state of the cells and hence the flux of nutrients through specific energy generating pathways. Amino acids fill several niches in embryo physiology, such as the use of glycine as buffer of intracellular pH (pHi). Several amino acids are also utilized as energy sources by the early embryo such as glutamine and aspartate. Aspartate can be utilized through the malate-aspartate shuttle, the significance of which during embryo development we are only beginning to understand. The thickness of the lines represents the relative flux of metabolites through that pathway. GLUTs, glucose transporters; GSH, reduced glutathione; LDH, lactate dehydrogenase; OAA, oxaloacetate; PDC, pyruvate dehydrogenase complex; pHi, intracellular pH; PFK, phosphofructokinase; PK, pyruvate kinase; PPP, pentose phosphate pathway. (B) *Metabolism of the blastocyst.* After compaction the embryo exhibits greatly increased oxygen consumption and an increased capacity to use glucose as an energy source. The increase in oxygen consumption plausibly reflects the considerable energy required for the formation and maintenance of the blastocoel, while the increase in glucose utilization reflects an increased demand for biosynthetic precursors. Consequently, there is a reduction in the ATP:ADP ratio, and a concomitant increase in AMP, which will have a positive allosteric effect on PFK, thereby facilitating a higher flux of glucose through glycolysis. Rather than oxidize the glucose consumed, the blastocyst exhibits high levels of aerobic glycolysis. Although this may appear energetically unfavorable, it does ensure that the biosynthetic arm of the pentose phosphate pathway (PPP) has maximum substrate availability at all times. Activity of the PPP will ensure reducing equivalents are available for biosynthesis and ensure production of glutathione (reduced), a key intracellular antioxidant. In order for high levels of glycolysis to proceed the blastomeres need to regenerate cytosolic NAD⁺. This can be achieved through the generation of lactate from pyruvate. A second means of generating cytosolic NAD⁺ is through the activity of the malate-aspartate shuttle. Although it is evident that blastocysts do use aerobic glycolysis, it is proposed here that the significant increase in oxygen utilization at this stage of development could be largely attributed to the activity of the malate-aspartate shuttle and the resulting demand for oxygen to convert intramitochondrial NADH to ATP. Indeed many tumors that exhibit aerobic glycolysis also have high levels of malate-aspartate shuttle activity. Furthermore, inhibition of this shuttle has dire consequences for subsequent fetal development. The thickness of the lines represents the relative flux of metabolites through that pathway. ACL, acetyl-citrate lyase; GLUTs, glucose transporters; GSH, reduced glutathione; LDH, lactate dehydrogenase; OAA, oxaloacetate; PDC, pyruvate dehydrogenase complex; pHi, intracellular pH; PFK, phosphofructokinase; PK, pyruvate kinase; PPP, pentose phosphate pathway. Adapted from Gardner, D.K. and Wale P.L. Analysis of metabolism to select viable human embryos for transfer. *Fertility and Sterility* 99, 2013, 1062–1072 with permission.

Fig. 3 (continued).

implantation. Day 1 pronuclear (PN) morphology and nucleolar precursor body (NPB) ratio, day 2 cell number, blastomere symmetry and nucleation and the ability to cleave from day 2 to day 3 appear to be the six most significant factors associated with subsequent fetal development.

Several studies have considered the relative weight of such cleavage stage morphological parameters and revealed that cell number, equal blastomere size and the number of mono-nucleated blastomeres on day 2 were the most predictive markers of blastocyst development and implantation potential. Rienzi et al., reported that cell number is the most critical factor determining the viability fate of the embryo, not only on day 2 but also on day 3, inferring that the optimal development can be defined as 4 or 5 cell on day 2 at 44–46 h post insemination, and more than 6 cells (7–9 cell) on day 3 at 66–68 h postinsemination (Rienzi et al., 2005). In agreement with such reports, the latest Cochrane review on cleavage stage versus blastocyst stage embryo transfer suggested that the most favorable group for blastocyst transfers were the good prognosis patient group that had higher number of 8 cell embryos on day 3 (Glujovsky et al., 2012). Evidence based data clearly demonstrates that several morphological features of the cleavage stages are associated with implantation potential and/or successful blastocyst formation.

Analysis of blastocyst morphology initially focused on the rate of expansion, and the determination of cell allocation to the two lineages of the inner cell mass (ICM) and trophoctoderm (TE). An advantage of assessing the blastocyst is that one is assessing the embryo proper (cleavage stage morphology reflects primarily oocyte competence). Determining the rate of expansion alone has physiological value, as the formation of the blastocoel is energetically demanding, and hence the embryo must possess a degree of metabolic competency to create the ionic gradient required to allow fluid to accumulate within the morula and coalesce to form a blastocoel. Analysis of the degree of expansion can be difficult after a blastocyst collapses. Interestingly, the thickness of the zona reflects each blastocyst's "expansion history," as an expanding blastocyst will induce changes to the shape of the surrounding zona, which does not revert back to its original form when the TE collapses.

Gardner and Schoolcraft (1999) therefore developed a comprehensive alphanumeric system, designed to incorporate the degree of blastocoel expansion, as well as the quality and cell number of the two cell lineages. Herein, blastocyst expansion rate is characterized by numbers from the early blastocyst to the hatched stage. Analysis of both the ICM and TE quality can then be performed for expanded blastocysts in which both cell types are clearly evident. ICM and TE quality were characterized by three grades, A to C. ICM grades: A, a tightly packed ICM with many cells; B, loosely grouped ICM with several cells, or C, very few cells and disorganized. TE grades: A, denoting TE with many cells forming a cohesive epithelium; B, few cells forming a loose epithelium; and C, very few large cells. (see Fig. 2 for the morphological characteristics of a 4AA blastocyst). Using this scoring system a strong correlation between the clinical outcome (implantation rates, pregnancy and twinning rates) and the morphological grade of blastocysts was established (Gardner et al., 2000). Subsequently, Ahlstrom and colleagues determined that although blastocyst expansion and ICM grade were significant predictors in both univariate and multivariate analyses, they were not predictors of live birth when analyzed by stepwise logistic regression, rather the TE was the most important determinant of successful transfer outcome (Ahlstrom et al., 2011). Such observations have been further supported by Ebner et al. (2016).

The physiology underlying the significance of the TE grade may reside in the significance of the TE during the initiation and progression of implantation, and that a healthy TE ensures acceptable implantation. A larger number of TE cells will be able to ensure greater signaling and interaction with the endometrium. Interestingly, although the TE produces human chorionic gonadotropin (hCG) as one of the earliest signals to the mother, it has recently been proposed that lactate production by the blastocyst, which will be derived primarily from the TE, has several key functions in regulating the implantation process (Gardner, 2015). These physiological roles endorse importance of a good TE grade in predicting implantation potential.

In spite of the importance of the TE grade, it remains important to include the ICM grade in order to determine true blastocyst quality, as it transpires that all three parameters of the blastocyst (degree of expansion, ICM and TE quality) are significantly associated with pregnancy and live birth rates (Van den Abbeel et al., 2013). Transfer of blastocysts with an “A” (top quality) grade ICM further reduces the incidence of pregnancy loss. Further, studies have also determined that ICM grade is positively associated with birth weight (Licciardi et al., 2015). Considering the quality of both the ICM and TE makes physiological sense as they do not exist in isolation, but rather coexist as a functional unit, whereby the TE which creates a unique environment for the ICM by the synthesis of blastocoel fluid, and the ICM itself that regulates the proliferation and activity of the TE (Ansell and Snow, 1975).

Analysis of Development and Viability: Screening for Aneuploidy

Through the development of blastocyst culture, it is now feasible to analyze biopsies taken from the TE of human embryos in order to determine the genetic constitution of the embryo (Schoolcraft et al., 2010). Technologies for the analysis of chromosome complement from a single or small group of cells has advanced significantly over recent years, and are now used worldwide to identify aneuploid embryos, thereby decreasing the time to pregnancy for patients of ages 38 and older (Gardner et al., 2015). However, even though this approach is able to identify aneuploid embryos to a high level of accuracy, not all euploid embryos are viable, and hence there remains considerable research into identifying biomarkers of viability (Sanchez et al., 2017).

Analysis of Development and Viability: Metabolism

Given the dynamics and complexity of embryonic metabolism, it is not surprising that should an embryo at any stage of development lose control of its energy production, i.e., if the flux of a specific nutrient through a metabolic pathway is altered to a significant degree, even for a brief period, then this is associated with significantly impaired development in culture and reduction of viability post transfer (Lane and Gardner, 2005). Proof of concept data was first reported in 1980 by Renard et al., who observed a positive relationship between glucose uptake by day 10 cow blastocysts and subsequent pregnancy after transfer (Renard et al., 1980). This relationship between blastocyst glucose uptake and the establishment of viable pregnancies was later confirmed in the mouse (Gardner and Leese, 1987). Early attempts to quantitate human embryo metabolism focused predominantly on the cleavage stages, given that it was not feasible to culture the human embryo to the blastocyst stage until the late 1990s. Hardy et al. (1989) reported that pyruvate uptake of embryos which arrested was lower than those which developed normally. With the development of more physiological media in the 1990s (Barnes et al., 1995; Gardner, 1994), it became possible to analyze the metabolism of the later stage embryo prior to transfer. Early studies revealed that blastocysts with the same alpha-numeric score, e.g., 3AA, from the same patient exhibited a wide range of glucose uptakes, indicating that morphological grade was not directly related to physiological status of the embryo (Gardner et al., 2001). Given the significance of glucose uptake by blastocysts in animal models, the uptake of glucose by individual human embryos on day 4 and 5, followed by single embryo transfer, allowed for the relationship between nutrient uptake and subsequent pregnancy to be established. Consistent with the animal data, glucose uptake by those embryos which were considered viable by the delivery of a healthy baby, exhibited a significantly higher glucose uptake on both day 4 and day 5 of development, thereby establishing in the human that embryo viability post compaction is positively associated with a high glucose uptake (Gardner et al., 2011) (Fig. 4). Furthermore, it was observed that female embryos consume significantly more glucose than males on day 4 of development. This phenomenon was previously reported in the mouse and attributed to the window in development in which both X-chromosomes are active in female embryos (Gardner et al., 2010; Gutierrez-Adan et al., 2006).

Glucose consumption of single post-compaction human embryos is predictive of embryo sex and live birth outcome. *Human Reproduction* **26**, 1981–1986 with permission.

As well as analysis of carbohydrates, Houghton et al. (2002) measured amino acid turnover by individual human embryos and observed different patterns of amino acid utilization between embryos that went on to form a blastocyst and those embryos that failed to develop. Those embryos that did develop, consumed more leucine from the culture medium, and the profiles of alanine, arginine, glutamine, methionine and asparagine flux were related to blastocyst formation (but not necessarily blastocyst quality). In a follow up study, Brison et al. observed changes in the levels of amino acids in the spent medium of human zygotes cultured for 24 h to the 2-cell stage. Asparagine, glycine and leucine were all significantly associated with clinical pregnancy and live birth (Brison et al., 2004). Subsequently it was determined that there also appear to be gender differences with regards to amino acid utilization (Picton et al., 2010; Sturme et al., 2010). Similar to the data on carbohydrate use, these data await validation in a larger patient population. Further, it is possible to use both data from time-lapse incubation, together with metabolic analysis of the embryo, to gain further insight into development and to facilitate selection models based on multiple parameters (Lee et al., 2015).

Conclusions

The preimplantation embryo resides within a changing environment in vivo, and undergoes dramatic morphological and physiological changes within the first 5 days of life, transforming from a single totipotent cell, to a blastocyst comprising of two distinct cell lineages. Underlying these changes are the transition from maternal to embryonic genome control, together with a shift from a metabolism based on low levels of oxidation of pyruvate, to one based on high levels of glucose uptake, which is subsequently metabolized by aerobic glycolysis (the Warburg effect). The commonality of glucose metabolism shared between blastocysts and cancers reflects their proliferation, and their ability to invade the endometrial tissue and establish a blood supply, while avoiding the maternal immune system (Gardner, 2015). Using physiological data, it has been possible to construct better culture media to support the development and viability of human embryos conceived through IVF, thereby increasing the overall success of this procedure. The ability to culture the human embryo to the blastocyst stage has not only led to higher success rates but facilitated the introduction of trophectoderm biopsy for preimplantation genetic screening. Analysis of embryonic kinetics and metabolism holds promise for identification of a viability marker to select embryos for transfer, and together with genetic screening, can help to reduce time to pregnancy for infertile couples.

Introduction

One of the main failures in assisted reproduction is the selection of the best embryo, a single embryo that is able to implant and thus reduce the risk of adverse outcomes related to multiple gestations. This has led to the incorporation of new technologies in in vitro fertilization laboratories, which aim to find specific embryo viability markers to select the best embryo, with greater implantation potential, without having a negative impact on pregnancy rates.

Historically, the embryo selection has been based on the morphological characteristics that occur at different stages of development. The most commonly used technique for embryonic evaluation is the serial evaluation through a standard microscope at certain developmental times, because it is considered specific, sensitive, and safe technique (Cummins et al., 1986; Scott, 2003). But it has negative consequences for embryo development: culture stability, observation frequency, limited available information (Payne et al., 1997). This results in a high degree of observatory-dependent subjectivity.

All this has been associated with relatively low success rates (pregnancy rate ~30% per transfer) (Andersen et al., 2009).

The use of morphokinetic parameters, obtained through time-lapse systems, together with the morphological parameters used so far, seems to be the best formula for embryo selection.

Time-Lapse Technologies Available on the Market

There are several time-lapse options available on the market: Primo Vision (Vitrolife) and The Eeva Test (Merck) consist of a microscope that is placed into the standard incubator. Other technologies, such as EmbryoScope (Vitrolife), Geri (Genea Biomedex), and Miri TL (Esco Medical) consist of a whole system integrated in a single equipment.

It is based in specially designed instruments, which take images of embryos every 15–20 min automatically, without having to take the embryos outside the incubator to minimize manipulation.

This also provides additional info to the embryologist, being able to evaluate embryos from a dynamic point of view by studying exact timings of some important parameters of the embryo.

Table 1 provides a summary of the technical characteristics of the different time-lapse models available in the market.

Time-Lapse Imaging and Morphokinetic

Single point morphological assessment of embryos and gametes are still considered the gold standard around the world. Technologies that are used to define embryo implantation potential or endometrial receptivity are purely subjective and imprecise.

Nowadays, embryologists use a combination of the traditional and sequential embryo morphological assessment with the intention to increase the precision of the diagnostics.

The selection of embryos to be transferred is based on the morphological criterion established in the work of the IVF laboratory: cell number, % fragmentation, asymmetry (Fig. 1). However, the study of cellular activity during the early stages of embryonic development provides additional information that can later be used in the selection process (Basile et al., 2012).

Table 1 Summary of technical characteristics of the different models of time-lapse available in the market

Technical characteristics	Primo Vision (Vitrolife)	The Eeva test (Merck)	EmbryoScope (Vitrolife)	Geri (Genea Biomedex)	Miri TL (Esco Medical)
Optics	Bright field	Dark field	Bright field	Bright field	Bright field
Microscope/ incubator	Microscope that can be placed in standard incubators	Microscope that can be placed in standard incubators	Incubators with integrated time-lapse	Incubators with integrated time-lapse	Incubators with integrated time-lapse
Embryo imaging	Pictures every 10 s	Pictures every 5 s	Pictures every 10 s	Pictures every 5 s	Pictures every 5 s
Focal planes	1	1	7	10	4
Capacity—patients	1/camera	1/camera	6/system	6/system	6/system
Embryo culture	16 group culture	12 group culture	12 individually culture	16 individually culture	14 individually culture
Data analyses	Manual	Real time	Manual	Manual	Manual

Fig. 1 Traditional morphological evaluation.

The first study based on time-lapse observations was published by [Payne et al. \(1997\)](#), where 50 fertilized eggs were observed. These eggs were chosen at random for time-lapse observation.

The study showed, it was possible to increase the time of observation, conserving the optimal conditions of culture.

Evaluations based on image analysis systems add objectivity to the process of embryo selection ([Basile et al., 2012](#)).

In contrast to the routine methods of embryonic evaluation traditionally used, time-lapse systems offer not only the precise determination of cell divisions but also the follow-up of morphological events such as appearance and resorption of fragments ([Van Blerkom et al., 2001](#); [Handarson et al., 2002](#)), formation of compaction, appearance of the blastocoe cavity and time of contraction of the blastocyst.

This helps us to avoid misinterpretations between a large fragment that could be confused with a blastomere, to categorize a 2PN fertilization when a third pronucleus may have been at some point and thus a series of events occurring throughout embryonic development.

The importance of the correlation between the number of cells and the stage of embryo development has been widely described. In recent years, the importance of knowing the time between fertilization and the first embryo division has become known, and can be used as an objective parameter that can be easily determined with some predictive value of embryonic viability ([Sakkas et al., 1998](#)).

In 1997, Shoukir was the first to demonstrate embryos had completed their division 25-h postinsemination (hpi) after conventional IVF had significantly better rates of gestation and implantation compared to those embryos that did not have been divided at this time.

In 1998, Sakkas published a study where he could verify that the results are the same as those published by Shoukir in embryos from ICSI cycles, where insemination times are more precise compared to traditional IVF.

In 2010, Wong et al. presented an analysis of 100 embryos that were cultured until day 5 or 6 of development, in which they correlated time-lapse imaging and molecular data throughout embryo development to the blastocyst stage. They found three morphokinetic parameters to predict blastocyst formation ([Cruz et al., 2012](#)) ([Fig. 2](#)):

- P1—Second cell cycle length: 14.3 ± 6.0 min (duration of the two-cell stage, CC2)
- P2—Synchrony of the second and third cell divisions: 11.1 ± 2.2 h (duration of the three-cell stage, S2) and
- P3—The duration of the second cell divisions: 1.0 ± 1.6 h (the cytokinesis giving rise to two daughter cells)

This study concluded that the development from the embryo to the blastocyst stage could be predicted with 94% sensitivity and 93% specificity after using these parameters. It was expected that embryos that did not meet one or more of these parameters would be stopped.

In 2011, Meseguer et al. published a study where optimal ranges were proposed for certain variables based in the analysis of 247 transferred embryos with known implantation (KID) that were culture in a time-lapse system, and it developed a hierarchical model that subdivided embryos into six categories from A to F. Categories from A to D were further subdivided into two subcategories (+) or (−).

The hierarchical classification begins with a morphological screening of the embryo cohort to eliminate those embryos that are clearly not viable (atresia, embryos that stop its development). These embryos are discarded and are not considered for transfer (category F).

Fig. 2 Model algorithm proposed by Wong et al. (2010). Three parameters were found as predictors of blastocyst formation: P1—duration of the first cytokinesis, P2—interval between the end of the first mitosis and the initiation of the second mitosis, and P3—the synchrony between the second and third mitosis. Adapted from Aparicio, B., Cruz, M., Meseguer, M. 2013. Is morphokinetic analysis the answer? *Reproductive BioMedicine Online* 27, 654–663.

The next step is to rule out embryos that meet any of the following exclusion criteria (i) DC: direct cleavage from zygote to the three-blastomere embryo, defined as: $cc2 = t3 - t2 < 5$ h, (ii) UBS: uneven blastomere size at the two-cell stage during the interphase where the nuclei are observable or (iii) MN: multinucleation at the four-cell stage during the interphase where the nuclei are visible (category E) (Fig. 3).

The subsequent levels for the model follow a strict hierarchy based on the binary timing variables $t5$, $s2$, and $cc2$. The precise timings of numerous morphokinetic parameters were identified considering microinjection as period zero. First cleavage was considered finished when the newly formed blastomeres were completely separated by a clearly defined membrane. Absolute time of division into two cells was called $t2$, to three cells $t3$, to four cells $t4$, and to five cells $t5$. Cell cycle duration was also evaluated, the second cell cycle ($cc2$) being the duration of period as a two-blastomere embryo (i.e., $t3 - t2$) and the degree of synchrony of the second cell division ($s2$), defined as the duration of the transition period from a two-blastomere embryo to a four-blastomere embryo ($t4 - t3$), which corresponds with the duration as the period as a three-blastomere embryo (Basile et al., 2012).

On the condition that the value of $t5$ is within the optimum range (48.8–56.6 h), the embryo is categorized as A or B. If the value of $t5$ is outside the desirable range (or if $t5$ has not yet been observed at 64 h), the embryo is categorized as C or D. If the value of $s2$ is within the ideal range (≤ 0.76 h) the embryo is classified as A or C depending on $t5$; similarly, if the value of $s2$ falls outside the favorable range, the embryo is categorized as B or D depending on $t5$. Lastly, the embryo is categorized with the extra plus (+) if the value of $cc2$ is within the favorable range (≤ 11.9 h) ($A+/B+/C+/D+$) and categorized with a negative value ($A-/B-/C-/D-$) if the value for $cc2$ is outside the optimal range (Figs. 3 and 4).

Fig. 3 Algorithm proposed by Meseguer et al. (2011). Developed a hierarchical model that subdivided embryos into six categories from (A) to (F). Four of these categories (A–D) were further subdivided into two subcategories (+) or (–).

(Meseguer *et al.* 2011)

Fig. 4 Model algorithm proposed by Meseguer *et al.* (2011). The model follows a strict hierarchy based on the binary timing variables t5, s2, and cc2. Adapted from Aparicio, B., Cruz, M., Meseguer, M. 2013. Is morphokinetic analysis the answer? *Reproductive BioMedicine Online* 27, 654–663.

In 2013, Conaghan *et al.* carried out a study where the utility of combining a time-lapse system with the traditional morphological evaluation for the selection of embryo was tested. Three distinct embryologists, from different centers, used two D3 evaluations (only morphology or morphology + time-lapse) to select which embryos in division would reach the blastocyst stage. As a result, when they used only morphology in D3, the three embryologists selected embryos with a specificity of 59.7%, 41.9%, and 79.5% and a positive predictive value (PPV) of 45.5%, 41.5%, and 50.5%. When time-lapse information was added to the D3 morphology, each embryologist improved his blastocyst selection to transfer with a specificity of 86.3% ($P < 0.0001$), 84.0% ($P < 0.0001$), and 86.6% ($P < 0.01$) and PPV of 56.3% ($P < 0.05$), 52.1% ($P < 0.05$), and 55.5% ($P = 0.34$).

In 2014, Rubio *et al.* published a study, where they validated the algorithm presented by Meseguer in 2011. In this study, 405 patients were chosen in the control group, in which the embryos were selected only by morphology and 438 patients in the study group, where the embryos were selected by the algorithm.

As a result, they had a significant increase in implantation rates in the study group (44.9%, 95% CI, 41.4–48.4) versus the control group (37.1%, 95% CI, 33.6–40.7).

In 2015, Basile *et al.* published a study presenting an improved version of the Meseguer algorithm. The study was divided into two phases. During the first phase, 754 KID embryos that had been selected only by morphological criteria were taken into account. They considered the morphokinetic data of these embryos and created an algorithm (variables: t3, cc2, and t5, criteria of exclusion: DC, UBS, and MN). In the next phase, the predictive capacity of this modern algorithm was tested, applying it to a fresh group of patients (885 cycles, embryos with known implantation = 1137).

As result, they obtained a significant decline in implantation rate when the embryo categories were reduced from A to E (A: 32%, B: 28%, C: 26.25%, D: 20.19%, and "E" 17% $P < 0.001$).

Is Morphokinetics Affected in Chromosomally Abnormal Embryos?

Basile *et al.* (2014) published a study combining time-lapse technology and PGS.

A total of 504 embryos were biopsied on day 3 of development and analyzed by arrayCGH, of these 143 had normal chromosomal content. Significant differences were observed between normal and abnormal embryos for t5, cc2, cc3, and t5–t2.

Embryos that were within the optimal range for t5 (47.2–58.2 h), cc3 (11.7–18.2 h), and t5–t2 (> 20.5 h) showed a significantly higher proportion of normal embryos than those outside these ranges.

The variables t5–t2 ($OR = 2853$; 95% CI, 1763–4616) and cc3 ($OR = 2095$; 95% CI, 1356–3238) were identified as the most relevant, related to normal chromosomal content. They created a hierarchical model that subdivided the embryos into four categories (A–D): if the value of t5–t2 falls within the optimal range, the embryo is categorized as A or B; if the value of t5–t2 falls outside the optimal range, the embryo is categorized as C or D. If the value of cc3 falls within the optimal range, the embryo is categorized as A or C depending on the value t5–t2; similarly, if the cc3 value falls outside the optimal range, the embryo is categorized as B or D, depending on t5–t2.

The algorithm increases the probability of selecting chromosomally normal embryos, although this by no means replaces the techniques of chromosomal analysis, such as array CGH (Fig. 5).

However, in that same year, Rienzi *et al.* (2014) published a study where a total of 455 blastocyst (day 5 or 6 development) were biopsied and analyzed performing real-time polymerase chain reaction.

In this study, they performed a hierarchical classification of euploid embryos based on the interval for completion of cleavage from 2 to 5 cells, and the duration of the third cell cycle (CC3) recently described by Basile *et al.* (2014).

Of 455 blastocysts analyzed, it was found euploidy in 186 (40.9%), single aneuploidy in 167 (36.7%), and complex aneuploidies in 102 (22.4%). Morphokinetic parameters of preimplantation embryo development were similar between euploid and aneuploid embryos.

No significant difference in the percentage of chromosomally normal embryos was found when embryos were divided into four categories according to the hierarchical classification proposed by Basile *et al.* (2014).

They concluded that PGS is currently the only diagnostic procedure for aneuploidy detection.

Fig. 5 An algorithm for embryo selection that classifies embryos from (A) to (D) with significant differences in the percentage of normal embryos. Based from Basile, N., Nogales, M.C., Bronet F., et al. 2014. Increasing the probability of selecting chromosomally normal embryos by time-lapse morphokinetics analysis. *Fertility and Sterility* **101**, 699–704.

Conclusions

In the last years many studies have been published where it is shown that the selection of embryos through kinetic markers improves reproductive results. Time-lapse technology is no longer an experimental tool, since there are many studies that support it.

The study of embryo kinetics through time-lapse systems, continue to give us new markers for embryo selection and has become a powerful tool to know the cellular activity that we could not see before using standard microscopes.

Many studies prove that kinetic information in conjunction with traditional morphology reduces interobserver variability and significantly enhances the embryologist's ability to select viable embryos with high implantation potential.

There are still many studies underway to evaluate and confirm the power of embryo selection, using time-lapse systems to obtain even higher rates of single live births at home, reducing multiple pregnancies. That is our goal. Time-lapse technology represents a powerful tool in AR.

Glossary

Chromosomal mosaicism Presence of two or more cell lines with different karyotypes within the same embryo. Either aneuploid mosaicism (two or more cell lines, all aneuploid) or euploid/aneuploid mosaicism (two or more cell lines, of which one is euploid) is possible.

Positive (or negative) clinical predictive value Rate of blastocysts predicted to be euploid (or aneuploid) after the comprehensive chromosome testing of a trophectoderm biopsy, that actually result in a full-term healthy life birth (or implantation failure).

Preimplantation Genetic Testing (PGT) Diagnostic methodology aimed at the detection of aneuploidies (PGT-A) and/or monogenic disorders (PGT-M) or chromosomal structural rearrangements (PGT-SR) in in vitro generated embryos.

Reproductive competence Potential of an embryo to result in a full-term live birth.

Preface

Preimplantation genetic testing (PGT) was introduced at the beginning of the 1990s as an alternative to prenatal diagnosis (PND) for the prevention of inheritable genetic disorders transmission in couples at increased reproductive risk. The first application of PGT was aimed at preventing the passing on of recessive X-linked disorders (e.g. adrenoleukodystrophy and X-linked mental retardation). To do this, sex chromosomes were detected and only female embryos were transferred ([Handyside et al., 1990](#)). Since then, genetic analysis techniques are undergoing continuous evolution and improvement. Indeed, we can report how it now encompasses the diagnosis of several recessive and dominant inheritable conditions. Given the recent increase of applications, as a basic concept, it is interesting to describe the difference between PGT for monogenic diseases (PGT-M) and chromosomal structural rearrangements (PGT-SR) and for aneuploidies (PGT-A).

PGT-M involves the detection of inheritable single gene mutations and/or unbalanced chromosomal aberrations. This type of testing is performed during an in-vitro fertilization (IVF) treatment cycle and it allows the identification of the embryos free of the genetic mutation that can be selected for transfer. To carry out this analysis, it is necessary that the cause of the genetic condition (mutation/chromosomal abnormality) had been identified in the affected parent. Nowadays, PGT-M can be considered a valid and established alternative to PND, as it can be employed for all genetic indications typically detected in PND. PGT-M is effective for single-gene disorders (genetic conditions that are the result of a single mutated gene), HLA typing, hereditary cancers-predisposing genes with variable penetrance (BRCA 1/2 status), late-onset genetic diseases (Huntington's Disease) and for some cases mitochondrial diseases. At present, over 4000 disorders have been linked to single-gene mutations; of these, the most common genetic conditions tested with PGT-M are Cystic Fibrosis, Tay-Sachs, Fragile X, Myotonic Dystrophy and Thalassemia. PGT-SR is an effective procedure for the detection of unbalanced derivatives from patients with chromosomal structural rearrangements. PGT-A is instead indicated for those couples at increased risk of producing embryos with chromosomal abnormalities, and can be employed also where no familial history of a genetic condition is present. Indications for PGT-A include:

- recurrent pregnancy loss (RPL), where patients have experienced 3 or more consecutive miscarriages after natural or assisted conception;
- repeated implantation failure (RIF), usually defined when patients have undergone 3 or more IVF treatments resulting in no embryo implantation;
- advanced maternal age (AMA), usually where the maternal age is above 35 years.

In PGT-A, embryo's karyotype is tested for the presence of aneuploidies (missing or additional part or entire chromosomes), the leading cause for implantation failure and increased miscarriage rate in women older than 35. The goal of PGT-A is to identify chromosomally-abnormal embryos and exclude them from transfer. By transferring only chromosomally-normal ones, the impact

of aneuploidies upon implantation failure and miscarriage can be excluded and the outcomes of IVF treatments can be significantly improved (Chen et al., 2015; Dahdouh et al., 2015).

Technical aspects and clinical implementation strategies of PGT techniques have evolved over the last decade. A critical issue for any PGT protocol is embryo biopsy. The biopsy procedure can be performed at different stages of embryo preimplantation development. Both embryo developmental stage at which the biopsy is performed and the characteristics of the cellular material retrieved have intrinsic features that impact diagnostic accuracy and post-biopsy embryo survival. Ideally, the gold-standard approach should be the least invasive and the most informative. Firstly, as for any new clinically-implemented technology, embryo viability and its reproductive potential must not be compromised. Secondly, the cellular material retrieved from the embryo must mirror the actual embryo genetic constitution with the highest possible accuracy, leading to a reliable genetic diagnosis and sufficient clinical positive predictive values.

In this chapter, the three main approaches for embryo biopsy will be examined: (1) polar body (PB) biopsy from the metaphase II oocyte and/or the zygote, (2) blastomere biopsy at the cleavage stage, and (3) trophectoderm (TE) biopsy at the blastocyst stage (see Fig. 1; Table 1 as a summary of the workflow of the different biopsy protocols, and Table 2 for pros and cons of each approach).

The ESHRE PGD consortium data from 2009 to 10 (Moutou et al., 2014) highlighted that blastomere biopsy alone accounted for almost 90% of the total number of biopsies, whilst TE biopsy was used in <1% of cases. Later, ESHRE data from 2012 to 13 showed a rapid shift from PB and cleavage stage biopsy procedures (approximately 2% and 75% respectively) towards blastocyst stage biopsy (increased to around 23% of all biopsies). This trend is foreseen to continue in the next years. In this chapter, the reasons behind this significant change in practice and the scientific evidence gained from preclinical and clinical studies over the last decade will be covered.

Blastomere Biopsy at the Cleavage Stage

Cleavage stage embryo biopsy is performed on Day 3 of in vitro development, when the embryo has between 6 and 10 cells. The procedure consists of opening the zona pellucida and collecting one blastomere that will be subjected to the genetic analysis (Table 1).

Zona opening can be performed by Tyrode acid, mechanical piercing, or laser-assisted methods. Clinical outcomes after the use of the three methods are similar, as it has been reported in several randomized controlled trials (RCTs) on sibling embryos (for a review see Cimadomo et al., 2016). However, the laser-assisted method is the most commonly used zona drilling technique, representing 75% of all biopsy procedures declared in the ESHRE PGD consortium data collection XII (Moutou et al., 2014). Probably, the reasons for the prevalence of laser-assisted method resides in its standardization and reproducibility, as it is less operator-dependent, less time-consuming and requires a shorter learning curve. Additionally, it has been shown that zona opening by laser does not appear to affect neither technical nor clinical outcomes (Taylor et al., 2010). Nevertheless, the procedure of zona pellucida opening can have an impact on subsequent preimplantation development affecting the hatching process and preventing embryo implantation. After zona pellucida opening, the removal of the selected blastomere is facilitated by the $\text{Ca}^{2+}/\text{Mg}^{2+}$ -free medium. The lack of these elements allows the loosening of cell-cell bonds, thus ensuring a less traumatic impact of the biopsy on the

Fig. 1 Polar body biopsy at Day 0/1 of preimplantation development (A–E); cleavage stage biopsy at Day 3 of preimplantation development (A'–E'); trophectoderm biopsy at the blastocyst stage (A''–E''). Zona opening is always performed using laser. A holding pipette anchors the embryos, whilst the biopsic specimen is collected using a biopsy pipette. The magnifications of the pictures are 20 × and 40 ×.

Table 1 Workflow of the different biopsy approaches

	<i>Day 0 Egg collection Insemination</i>	<i>Day 1 fertilization check</i>	<i>Day 3 cleavage stage</i>	<i>Day 5 blastocyst</i>	<i>Day 6 blastocyst</i>	<i>Day 7 blastocyst</i>
Polar body biopsy	Biopsy of 1st polar body (prior to ICSI)	Biopsy 2nd polar body (post fertilization check)	Fresh transfer and/or cryopreservation	Fresh embryo transfer and/or cryopreservation		
Blastomere biopsy	–	–	Zona drilling and blastomere biopsy	Fresh embryo transfer and/or cryopreservation		
Trophectoderm biopsy approach 1	–	–	Zona drilling	TE biopsy and cryopreservation if no fresh transfer Slower embryos remain in culture	Fresh embryo transfer TE biopsy of additional embryos and cryopreservation	TE biopsy of additional embryos and cryopreservation
Trophectoderm biopsy approach 2	–	–	–	Sequential zona drilling, TE biopsy and cryopreservation if no fresh transfer Slower embryos remain in culture	Fresh embryo transfer Sequential zona drilling, TE biopsy of additional embryos and cryopreservation	Sequential zona drilling, TE biopsy of additional embryos and cryopreservation
Trophectoderm biopsy approach 3	–	–	–	Zona drilling + monitoring until the hatching of few TE cells, biopsy and cryopreservation if no fresh transfer Slower embryos remain in culture	Fresh embryo transfer Zona drilling + monitoring until the hatching of few TE cells, biopsy and cryopreservation if no fresh transfer	Zona drilling + monitoring until the hatching of few TE cells, biopsy and cryopreservation if no fresh transfer

embryo. However, negative effects of Ca^{2+} -depleted media have also been reported, with impacts on the compaction process, cytoskeleton remodeling and intercellular communication mechanisms (Sefton et al., 1996). Additionally, there is growing evidence that even at this early developmental stage, human embryos cells are already committed to a specific lineage and the removal of one random blastomere can interfere with cell differentiation processes and embryo's ability to correctly develop and implant. From an operational point of view, these variables are likely to reduce both clinical reproducibility and technical standardization of the approach. Moreover, one study demonstrated that zona pellucida drilling and blastomere removal compromise the hatching process and lead to the development of smaller and delayed blastocyst, with a thicker zona pellucida (Kirkegaard et al., 2012). Clear evidence about the detrimental effects of cleavage stage biopsy on embryo reproductive competence was provided by a randomized paired study performed by Scott et al. (Scott et al., 2013). In their investigation, they compared the implantation rate of sibling top quality embryos obtained from the same stimulation cycle, transferred in double ETs, where one of them was randomized for biopsy and the other used as paired control. The identity of the implanted embryo was confirmed by DNA fingerprinting performed on the biopsied cell and the fetal DNA. Thanks to this elegant design, they demonstrated a dramatic 39% relative decrease in implantation rate after blastomere biopsy, revealing that cleavage stage biopsy approach does compromise embryo reproductive competence.

Despite nowadays robust genetic technologies are available for the analysis of low DNA input samples, cleavage stage biopsy still suffers from technical and biological drawbacks associated with single cell analysis. Specifically, the fact that embryo's genome is represented in a single set derived from a single cell can give rise to technical problems, should some of the DNA be lost or degraded during blastomere collection. The lack of certain parts of the genome could lead to the generation of artifacts. This occurrence potentially causes false positive and false negative results, thus compromising the reliability of the diagnosis. These artifacts can give rise to erroneous analysis, as from a few loci to whole chromosomes could be under- or over-amplified. These types of misdiagnosis include: (i) Allele drop-out (ADO, random loss of one allele in favor of the other variant); (ii) Preferential amplification (PA,

Table 2 Comparison between the 3 different biopsy methods

<i>Polar body biopsy</i>	<i>Day 3 blastomere biopsy method</i>	<i>Day 5/6/7 TE biopsy method</i>
PROs • Analysis performed on waste products of female meiosis • Compatible with fresh ET after genetic diagnosis • Allowed in those countries where embryo biopsy is not.	• Vast experience worldwide • Embryos reach the cleavage stage in a synchronous fashion (day 3 of preimplantation development) • Standardized approach • Compatible with fresh ET	• Selection of TE cells to biopsy. The ICM is not involved • Robust diagnosis (5–10 cells are retrieved and analyzed) • High compatibility with TLM and single media culture systems • No impact on embryo reproductive competence • Highly cost-effective (biopsy of developmentally-competent embryos only) • Low amplification failure rate ($\approx 1\%$) • The IVF laboratory must be experienced in extended embryo culture and vitrification. • Limited experience worldwide
CONS • Analysis limited to the maternal genome (excludes paternal genome and potential mitotic errors) • Biopsy and analysis of both PBs required (time-consuming and not cost-effective procedure) • Technical issues associated to single cell-based analysis • High amplification failure rate ($\approx 10\%$)	• High impact on embryo reproductive competence • Technical issues associated with single cell-based analysis • Lowest diagnostic reliability • High amplification failure rate ($\approx 10\%$)	

ET, embryo transfer; TE, trophectoderm; ICM, inner cell mass; TLM, time lapse microscopy; PBs, polar bodies.

over-amplification of specific genomic regions or even of whole chromosomes); (iii) Chimerical DNA molecules formation; (iv) high rate of DNA amplification failure (Harton et al., 2011).

Furthermore, none of the contemporary molecular methods for single-cell analysis can distinguish between a cell in G1-, S- or G2/M-phase of the cell cycle. This limitation can inevitably give rise to false negative/positive results in the case a cell is at an intermediate point of the S-phase (DNA replication phase), when it is processed (Van Der Aa et al., 2013).

From a diagnostic point of view, one of the main limitations of cleavage stage biopsy is chromosomal mosaicism, which consists in the coexistence of two or more karyotypically different cell lines in the same embryo. This is caused by mitotic errors occurring in a cell at any point after the first cell division. This process is mainly induced by aberrant cell-replication mechanisms such as anaphase lagging, non-disjunction, endoreplication and structural events of DNA damage of chromatid/chromosome breakage leading to structural rearrangements (e.g. translocations) or segmental aneuploidies (Coonen et al., 2004; Daphnis et al., 2005). Mosaicism has been reported to reach its highest level at this stage of preimplantation development, but all the reported estimates of mosaicism are impacted by the low technical accuracy of the methods used to detect aneuploidy (e.g. FISH). In fact, the estimated rates that have been published to date range from 10 up to 90% (Capalbo et al., 2016b) and are likely overestimated, considering the much lower incidence of mosaicism detected in spontaneous conceptions (1.22%) and in IVF pregnancies (1.32%), where true fetal mosaicism accounts only for 0.3%–0.44% (Huang et al., 2009).

The limited predictive power for embryo implantation that derives from blastomere analysis was clearly highlighted in an important study where its positive clinical predictive value was assessed (Scott et al., 2012). This study showed that the rate of euploid embryos leading to a sustained implantation after a cleavage stage PGT-A diagnosis is lower than 30%.

In conclusion, despite the vast experience in its use worldwide, cleavage stage biopsy is going to be gradually abandoned, given the large evidence on the technical limitations of single cell analysis and the detrimental effect of the biopsy procedure on the embryo.

Polar Body Biopsy

Polar body (PB) biopsy is a diagnostic approach that was proposed as a valuable alternative to cleavage stage biopsy. The main reason behind this method was that embryonic aneuploidies are mainly derived from oocyte meiotic errors (Hassold and Hunt, 2001; Heffner, 2004). These chromosomal aberrations are accumulated during oocyte's meiotic arrest that lasts until ovulation and remain the main cause of the age-associated decrease of female fertility. Advantages of this approach include the fact that the analysis is performed on waste products of female meiosis without directly involving the embryo, and it is compatible with fresh ET after genetic diagnosis. Additionally, PB biopsy is the only PGT-A method that can be performed in those countries where embryo biopsy is not allowed at any stage of preimplantation development after fertilization.

PB biopsy consists in removing both the first and second PB, at different time points (the first before ICSI and the second at the time of fertilization check around 16 h after insemination) or by a simultaneous approach 16 h after ICSI or after the appearance of

the two pronuclei (PN) (Table 1). The detection of the PN prior to PB biopsy ensures that the zygote's meiotic process is concluded, thus minimizing the risk of enucleation.

The methods for zona drilling during PB biopsy are the same as previously described for blastomere biopsy.

Conflicting data have been reported when dealing with the impact of PB biopsy on subsequent embryo development and no comprehensive study is yet available on embryo implantation potential following PB biopsy. Some papers report no negative effect on oocyte/embryo quality parameters, including oocytes lysis and activation rates, embryo chromosome breakage incidence after calcium ionophore treatment and Tarkowski preparation or on neonatal outcomes. On the other hand, one study reported impaired preimplantation embryo development following PB biopsy, showing higher embryo fragmentation rate, lower embryo quality, higher cleavage arrest rate, and lower mean number of blastomeres on Day 3 compared to the control group (for a review see Cima-domo et al., 2016). However, data about embryo implantation potential was not reported in this study.

The ESHRE PGD Consortium data reports that, since its introduction, PB biopsy never exceeded 10%–15% of all the PGT-A/PGT-M procedures performed in Europe. Nowadays, its application is further decreasing probably due to the number of studies highlighting technical, economical, biological, and clinical limitations underlying this approach.

The main shortcoming of PB biopsy is that the genetic investigation is limited to the maternal genome, excluding both paternal genome contribution and potential post fertilization mitotic errors from the analysis. The reference study highlighting the biological and technical limitations of PB biopsy was published in 2013 (Capalbo et al., 2013a). It was designed as a sequential biopsy associated to aCGH analysis of PBs, blastomere and TE from the same embryo. The data generated led to a comprehensive view on chromosomal segregation patterns from female meiosis and throughout preimplantation development up to the blastocysts stage in advanced maternal age patients. Additionally, it provided the unique possibility to infer the accuracy of PB-based chromosome testing in predicting the chromosomal complement of the resulting embryos. Firstly, this study demonstrated that the procedure is time-consuming and not cost-effective, due to the need of investigating both polar bodies to have a prospect of the oocyte chromosomal contribution to the embryo. In fact, approximately half of oocyte-derived aneuploidies in embryos arise due to segregation errors in the second meiotic division (Ottolini et al., 2015). Secondly, PB diagnostic accuracy in detecting the karyotype of the resulting embryos was questioned. Specifically, on a chromosome basis, concordance between PBs and blastocyst chromosomal complement was as low as 60%. The authors reported high false positive and false negative rates in PB-based diagnoses due to the lack of information regarding paternally- and post-zygotic mitotically derived aneuploidies, as well as meiotic errors corrected at later stages of embryo development. These intrinsic biological and technical limitations of PB analysis compromise its diagnostic accuracy, potentially resulting in either the discarding of reproductively competent embryos, or in the transfer of chromosomally-abnormal ones. Other authors also described a consistent proportion ($\approx 20\%$) of chromosome segregation errors (Handyside et al., 2012) and 17% false positive rate in PB diagnoses, with chromosomal copy number changes in PBs not reflecting the karyotype of the ensuing zygote (Christopikou et al., 2013). Other concerns on PB-based PGT relate to the difficulty in detecting precocious separation of sister chromatids (PSSC) errors balancing in MII and causing reciprocal polar body aneuploidies (Forman et al., 2013).

In synthesis, all this evidence resulted in the gradual abandonment of PBs biopsy approach, in favor of the blastocyst stage one.

Trophectoderm Biopsy

There are three published TE biopsy protocols in the literature. The first was published by McArthur and colleagues in 2005 (McArthur et al., 2005), the second by Capalbo et al. in 2014 (Capalbo et al., 2014), and the third, which is an adaptation of the previous two, by Capalbo in 2016 (Capalbo et al., 2016a). The first method entails a laser-assisted zona pellucida drilling step at the cleavage stage, followed by extended culture to the blastocyst stage. On Day 5, expanded blastocysts (including those with herniating TE cells) can be biopsied, whilst cavitating morulas and early blastocysts are maintained in culture and biopsy is attempted 24 h later. The zona opening at the cleavage stage was thought to promote an artificial TE cells herniation on Day 5 or 6, thus facilitating the TE separation during the biopsy. Although this approach is still the most commonly used, it shows two important drawbacks: (i) The embryo is removed from the incubator twice; the first time, on Day 3 to open the zona pellucida, the second time, at the blastocyst stage when the biopsy is performed (Table 1) (hence, this approach entails an additional exposure of the embryo to suboptimal culture conditions, increasing the risk of impairing its preimplantation development, impacting zona pellucida thinning, blastocyst expansion and overall TE cells count); (ii) There is a risk that the ICM herniates from the opening produced on Day 3, making the biopsy a more challenging procedure.

The second protocol does not entail any manipulation on Day 3 of preimplantation development, so that the embryo is left undisturbed until the blastocyst stage. Blastocyst hatching is not artificially-induced and it is left to occur spontaneously. This strategy allows the selection of the portion of TE to biopsy, rather than having to target the cells extruded through the zona opening. In practice, Day 5 zona opening is performed when the ICM is clearly visible thus not to involve it in the biopsy process. Additionally, undisturbed culture conditions provide a good synchronization of the blastocysts to be biopsied on Day 5, 6 or 7 of preimplantation development, and it is well-suited with the use of a single media-based and/or a time-lapse microscopy-based culture system.

At last, for IVF centers that introduce this approach for the very first time, it can be initially adopted a Day 5/6 hatching strategy as described by Capalbo and colleagues in 2016. In this case, when the blastocyst is fully expanded is removed from the incubator and the zona pellucida is drilled using a laser, then the embryo is returned to the incubator. This intervention boosts the herniation of the TE cells close to the hole in the following hours. Subsequently, these cells are removed from the body of the blastocyst by

micromanipulation, combining gentle suction via the mouth-controlled pipette and dissection via laser beam. This alternative TE biopsy approach may be easier for unexperienced practitioners as it divides the procedure into two separate steps, whilst avoiding the drawbacks of Day 3 zona opening.

The paired randomized study by Scott and colleagues discussed above represents a landmark paper in this field (Scott et al., 2013). In this study, differently from embryos biopsied on Day 3, implantation rates of embryos biopsied on Day 5 were comparable to those of sibling non-biopsied blastocysts. This evidence about the safety of the procedure represented a milestone for the growing application of TE biopsy. The reasons for a higher stress-tolerance of the embryo at this stage of preimplantation development are mainly three: TE is the non-embryonic part of the blastocyst, the biopsy takes place after embryonic genome activation (Day 3) and a limited portion of the embryo biomass is removed (5–10 cells out of ≥ 200).

A diagnosis obtained from a randomly selected TE sample biopsy is extremely accurate. Blastocyst stage biopsy ensures a more robust diagnosis than previous approaches because multiple cells (5–10) are retrieved and analyzed from the embryo. Specifically, all validation studies published to date based on TE biopsy and comprehensive chromosomal screening (CCT), reported 98%–100% of correct prediction of meiotic errors (e.g., Capalbo et al., 2013a; Capalbo et al., 2013b; Fragouli et al., 2011).

Recently, the reliability of blastocyst stage aneuploidy testing using different CCT methods was assessed (Capalbo et al., 2015). This study was designed as a qPCR-based blinded reanalysis of several blastocysts previously diagnosed as aneuploid by aCGH. Whenever a discordant diagnosis was detected, a third biopsy and array-SNP analysis were conducted to define which platform was more prone to false positive/negative results. Importantly, on a chromosome analysis, a consistency of 99.8% between the three CCT methods was reported.

The presence of chromosomal mosaicism in preimplantation embryos, and its impact on the reliability of PGT-A diagnosis are at the center of current debate. In euploid/aneuploid mosaic embryos, aneuploid cells are randomly allocated across ICM and TE as showed by the almost full concordance between the chromosomal constitution of the two cell lineages in several studies (reviewed in Capalbo and Rienzi, 2017; Capalbo et al., 2016b). Moreover, a clear definition of the incidence of mosaicism in blastocyst staged embryos, and the risk of misdiagnosis associated, has been reported in at least four studies and reported to be around 4%–5% (Capalbo et al., 2016b).

A last interesting point deals with the implementation of blastocyst biopsy approach in the clinical practice. From an economic and logistic perspective, this approach currently represents the most cost-effective. Indeed, differently from PB and cleavage stage biopsies, blastocyst biopsy is performed only on developmentally-competent embryos (at least capable of blastocyst development), thus focusing operations and associated costs to the analysis of embryos with demonstrated developmental potential.

Laboratory Requisites for PGT

In the IVF laboratory, certain basic, nonetheless critical prerequisites are required to allow the safe implementation of a blastocyst stage biopsy approach. First, the IVF laboratory must be already experienced and set up for extended embryo culture. An appropriate number of incubators must be present to sustain the workload. It is recommendable not use the incubators at their maximum capacity as this would entail sub-optimal culture conditions (due to shorter recovery time for CO₂ and O₂ levels after each opening) and downstream effects on embryo development. Based on the most compelling scientific evidences recently published, the use of low oxygen tension should be considered mandatory for blastocyst culture (Wale and Gardner, 2016). Furthermore, blastocyst cryopreservation must be an already established, optimized and effective practice before blastocyst biopsy can be implemented in the laboratory. For these reasons, TE biopsy approach is probably perceived as more complicated, less reproducible and standardized than blastomere biopsy. For instance, embryos reach the blastocyst stage in an asynchronous fashion (Day 5–Day 7 of preimplantation development) and they are characterized by heterogeneous morphology. Nevertheless, several papers in the last decade showed no significant correlation between blastocyst aneuploidy rate and embryo developmental rate or static/dynamic morphological evaluation (Capalbo et al., 2014; Rienzi et al., 2015). These data indirectly suggest that every embryo that reaches the blastocyst stage should be biopsied, regardless their morphological grading.

Concluding Remarks and Future Perspectives

According to the data available in the literature, TE biopsy appears to be the most accurate and effective method for PGT purposes. Indeed, from ESHRE PGD consortium data, it is possible to appreciate how TE biopsy is gradually replacing both cleavage stage and PB biopsy approach, and its clinical implementation is expanding worldwide. Specifically, TE biopsy sharply increased from < 1% of the total number of biopsy procedures performed in Europe in 2009–10 to almost 23% in 2012–13. Indeed, over the last decade, PGT-A and PGT-M/SR application has sharply increased. Substantial improvements in embryo biopsy, and cytogenetic and molecular biology techniques were essential to for a more generalized implementation of these strategies. Further improvement will derive from the continuous monitoring of oocyte/embryo quality parameters and clinical outcomes to evaluate the accuracy and efficacy of different PGT methodologies.

Finally, non-invasive or less-invasive methods to perform preimplantation genetic testing are under investigation, namely the evaluation of liquid biopsies as blastocoel fluid and spent blastocyst media as alternative sources of embryonic DNA. Moreover,

novel information could arise in the next years to increase our predictive power upon implantation from static and dynamic blastocyst morphological evaluation in time-lapse, as well as proteomic/metabolomic screening of spent culture media.

Introduction to Physiologic Hatching

Normal preimplantation embryo development requires the developing blastocyst to hatch out of its glycoprotein “shell”—the zona pellucida—before the embryo can interact with and implant into the endometrium (Sun et al., 2012). The physiology of this process is a coupling of the development and expansion of the blastocoel cavity with the thinning, and eventual disruption of the zona pellucida (Gardner and Schoolcraft, 1999) as a result of lysins released by the embryo and endometrium (Montag et al., 2000). Cavitation and the consequent blastocoel result from gradients generated from ion transport by Na–K-ATPase activity in the trophoblast epithelium in conjunction with relative permeability of tight junctions between trophoblast cells (DiZio and Tasca, 1977; Gardner et al., 2000; Maitre et al., 2015). As a sodium gradient is generated by the Na–K-ATPase on the basolateral membrane, water follows and the blastocoel is created. As this process continues, hydrostatic pressure within the blastocoel increases resulting in blastocyst expansion and eventually hatching (Câmara et al., 2016) through the zona which has been concurrently thinned in response to lytic enzymes from the trophoblast and uterine cavity. Blastocyst expansion, a subjective assessment of the degree an embryo has hatched, is commonly incorporated into morphological assessments of embryo viability (Gardner et al., 2000) (Fig. 1).

The first component of the gardner/schoolcraft grading system (Gardner and Schoolcraft, 1999), the extent of blastocyst expansion and hatching, has shown to be predictive of embryo transfer outcomes in both fresh and frozen transfers (Goto et al., 2011; Gardner et al., 2000; Schoolcraft et al., 1999) with more expanded and/or hatching blastocysts at the time of assessment being more likely to lead to a successful pregnancy. As the elasticity and thickness of the zona pellucida varies between different patients' oocytes

Fig. 1 Blastocysts at various stages of hatching. Top left: As the blastocoel expands, the zona pellucida is stretched thin. (B) Identifies the blastocoel. (TE) Identifies the trophoblast. Top right: Once the zona pellucida is breached the embryo begins to “hatch” out from the zona pellucida. The thickened zona in this hatching blastocyst suggests that the embryo underwent assisted hatching. Bottom left: The completely hatched blastocyst without a zona pellucida. Bottom right: The completely hatched blastocyst adjacent to its zona pellucida. From Barry Behr's (coauthor) Laboratory.

and embryos and changes throughout maturation, fertilization, and preimplantation development, some hypothesized that it was an abnormally thick or persistently rigid zona pellucida that explained the observed differences in clinical outcomes between less expanded and hatching blastocysts. Accordingly, a particularly restrictive zona pellucida could be the root cause of certain patients' infertility and poor outcomes with in vitro fertilization, not allowing the embryo to interface directly with the endometrium. This rationale formed the basis for using assisted hatching to overcome the theorized pathologic zona pellucida.

Assisted Hatching Techniques

Mechanical dissection: First described in clinical use in the 1980s by Cohen et al., assisted hatching is a micromanipulation procedure intended to help the developing embryo hatch from the zona pellucida so that it can interface directly with the endometrium (Cohen et al., 1990). While the zona is critical for early developmental events including fertilization and transport through the fallopian tubes (Bleil and Wassarman, 1980) and possibly even protection from microorganisms and the maternal immune system (Zhao and Dean, 2002), proponents of assisted hatching argue that many viable embryos are constrained by an abnormal zona impenetrable to the developing embryo. As these presumed viable embryos never have an opportunity to interface directly with the endometrium, the impenetrable zona pellucida causes these embryos' reproductive failure. As the zona is thought to have no beneficial role in implantation, its persistence was deemed only a potential hindrance to patients and facilitating the hatching process either by thinning or creating a complete opening in the zona has been presumed to be therapeutic. In the aforementioned initial trial, the zona was incised mechanically with a microneedle at two points and those patients who transferred embryos that were hatched had significantly higher implantation, clinical and ongoing pregnancy rates than patients who transferred embryos that had not undergone assisted hatching (Cohen et al., 1990).

Zona Drilling

Due to occasional trapping or damage to the developing embryo when using the microneedle method and inconsistencies in its application, the assisted hatching technique was then refined by some of the same authors who performed the zona breach by "drilling" the glycoprotein layer with acid tyrode's solution through an ICSI micropipette (Cohen et al., 1992), dissolving targeted areas in the glycoprotein layer. The practice of drilling with acid tyrode's had been previously used to remove or thin the zona pellucida to aid fertilization or facilitate embryo biopsy in animal models (Gordon and Talansky, 1986) as well as with early animal experimentation with assisted hatching (Malter and Cohen, 1989). During drilling, the embryo is stabilized with a holding pipette while a $\sim 10\text{ }\mu\text{m}$ micropipette is placed against the zona adjacent to an empty area of perivitelline space at the 3 o'clock position. Acid tyrode's is then slowly directed against the zona until an opening is seen. Some aim to create an opening in the zona as large as $30\text{ }\mu\text{m}$, while others describe a $10\text{--}13\text{ }\mu\text{m}$ inner breach and a $15\text{--}18\text{ }\mu\text{m}$ defect at the zona surface (Balaban et al., 2002; Jones et al., 2006). Others have advocated for thinning the zona or partial zona dissection rather than creating a complete opening (Khalifa et al., 1993). The heterogeneity in application of even a single method of assisted hatching makes it difficult to analyze the efficacy of the practice in general. Following zona drilling, embryos are rinsed repeatedly to wash away the acidic solution ($\text{pH} < 3$). Cohen's randomized controlled trial employing zona drilling did not benefit the general patient population, however a subanalysis confined to only patients with a relatively thickened zona pellucida ($\geq 15\text{ }\mu\text{m}$) demonstrated that patients who underwent zona drilling had significantly higher implantation rates than those who did not (Cohen et al., 1992). This supported the notion that assisted hatching benefits those patients who have poor prognoses due to an abnormally thick or restrictive zona pellucida. Advocates for therapeutic assisted hatching posited that the improved implantation rates observed for embryos subjected to the micromanipulation technique may be due to the overcoming the hardening associated with embryo culture in vitro (DeMeestere et al., 1997). Others argued that assisted hatching promoted earlier expansion and hatching of the blastocyst, potentially resynchronizing the developing embryos with the premature window of implantation encountered in fresh transfers after ovarian stimulation, while others explanations included the facilitating the exchange of growth factors and other messengers between the peri-implantation embryo and the endometrium (Nikas et al., 1999; Martins et al., 2011).

Laser Assisted Hatching

Due to observed improvements in pregnancy rates among poor prognosis patients, refinements in the hatching technique continued. The use of lasers to perform hatching is the most recent technique employed. Initially requiring direct contact of the pipette with the zona, more recent applications now offer noncontact laser diode methods which can be performed without any manipulation with holding or micropipettes, offering improved efficiency (Rink et al., 1996; Schöpper et al., 1999). Laser assisted hatching uses photoablation to create a breach in the zona. As the laser is highly absorbed by the media, the thermal effect is localized adding precision and consequent safety (Germond et al., 1996; Belil and Veiga, 2012). When applied to cleavage stage embryos prior to transfer, the embryos are placed in HEPES-buffered media on an inverted microscope capable of laser assisted hatching. An area of zona pellucida adjacent to an area between blastomeres is optimal for aiming the laser to minimize the risk of thermal injury to cells. Short pulse durations $< 5\text{ ms}$ and mild power $< 100\text{ mW}$ may also improve the safety profile of this practice (Douglas-Hamilton and Conia, 2001). In sibling embryo studies, subsequent embryo development after laser assisted hatching has shown to be comparable to those hatched with acid tyrode's (Jones et al., 2006) (Fig. 2).

Fig. 2 Example of hatched cleavage stage embryo. Received from Hamilton Thorne.

Clinical Outcomes

Since its first incorporation into assisted reproduction, assisted hatching has been increasingly utilized, being incorporated in over half of day 3 fresh transfers and 22.8% of fresh blastocyst transfers. This increase utilization is most notable in the population of patients older than 38 years old or with a history of least two prior failed ART cycles (Kissin et al., 2014); however with the increasing incorporation of embryo biopsy in ART, patients undergoing PGS/PGD are likely the fastest growing patient population utilizing assisted hatching.

Despite its prevalent use by patients undergoing in vitro fertilization, the data supporting assisted hatching is inconsistent. It is unclear whether this is due to the heterogeneity among assisted hatching methods, applications, and indications studied, or whether its practice is not entirely justified. The most recent Cochrane review on assisted hatching analyzed 31 randomized controlled trials evaluating assisted hatching: the indications for assisted hatching in the trials were as diverse as the outcomes between trials. Among all studies included, the clinical pregnancy rate was significantly improved for the assisted hatching cohort (OR 1.13, 95% CI 1.01–1.27). Only nine randomized controlled trials reported live birth as an outcome, and analysis of these studies did not find any increased likelihood of live birth or clinical pregnancy attributed to assisted hatching (Carney et al., 2012). In another meta-analysis consisting of 28 randomized controlled trials, among all-comers there was a trend towards an increased pregnancy rate among patients whose embryos underwent assisted hatching (RR = 1.11, 95% CI = 1.00–1.24), although in the subgroup analysis, patients with fresh embryos transferred to women with previous repeated failure and frozen-thawed embryos transferred to unselected or non-poor prognosis women, there was a significantly increased pregnancy rate associated with assisted hatching. Among the 16 trials which reported live birth, there was not a significant benefit in the assisted hatching cohort however, the pooled analysis of 2 trials which facilitated a subgroup analysis of patients with previous repeated IVF failures did demonstrate a significantly improved live birth rate in the assisted hatching cohort (RR = 2.51, 95% CI = 1.06–5.96) (Martins et al., 2011). Based on this conflicting data, the practice committee of the American Society for Reproductive Medicine has concluded that there is insufficient evidence to conclude that assisted hatching improves live birth (Medicine and Technology, 2014), although some of the subgroup analyses from these studies still leaves its utility for patients with poor prognoses and previous repeated IVF failures open for debate.

Timing of Assisted Hatching

Due to the claimed benefit of alleviating viable embryos from an overly restrictive zona pellucida, assisted hatching has historically been incorporated into clinical practice at the cleavage stage before a cleavage stage embryo transfer on day 2 or day 3 of culture; however, there have also been studies advocating performing hatching at both the cleavage and blastocyst stages after thawing (Hiraoaka et al., 2007; Balaban et al., 2006; Wan et al., 2014). Additionally, with the advent of single step culture media and purported benefit of uninterrupted culture, performing assisted hatching at the fertilization check has even been described (Behr, unpublished data).

Use in Conjunction With Embryo Biopsy

As preimplantation genetic screening and diagnosis is being increasingly utilized by patients undergoing in vitro fertilization, techniques for embryo biopsy have become increasingly important. While cleavage stage embryo biopsy has largely been replaced by

trophectoderm biopsy, it is still occasionally used and penetrating the zona pellucida with one of the aforementioned assisted hatching methods at the time of biopsy is required. For patients planning trophectoderm biopsy, assisted hatching at the cleavage stage is frequently incorporated in order to maximize the number of embryos reaching the hatching or hatched blastocyst stage (Lee et al., 2015; Khalifa et al., 1993), facilitating an easier trophectoderm biopsy. While a safer embryo biopsy is the priority and chromosomal screening is likely a more sensitive screening tool than morphology based grading (Forman et al., 2013), by performing assisted hatching on these embryos it likely confounds the use of blastocyst expansion as an embryo selection method. This is demonstrated by the observation that blastocyst hatching status is not predictive of implantation after embryo biopsy (Rodriguez-Purata et al., 2016).

Adjuvant Treatments With Assisted Hatching

Since the first descriptions of incorporating assisted hatching into clinical use, investigators have been proponents of transfer recipients being treated with corticosteroids and antibiotics prior to embryo transfer (Cohen et al., 1990). Without an intact protective glycoprotein shell, advocates for these treatments were concerned that embryos with a breached zona may be particularly vulnerable to the maternal immune response or microbial contamination. Embryos that do not undergo assisted hatching must also hatch prior to implantation, and studies investigating the benefit of immunosuppression and prophylactic antibiotics have not consistently demonstrated a benefit (Lee et al., 1994; Polak de Fried et al., 1993). Despite inconsistent evidence, many providers have continued to provide antibiotics and corticosteroids to patients whose transferred embryos are exposed to the maternal environment prematurely due to assisted hatching, ICSI or embryo biopsy. In one randomized controlled trial, patients with a poor prognosis of success, previous implantation failures or transfers of cryopreserved embryos were randomized to receive assisted hatching with and without antibiotics and corticosteroids. The results were inconsistent, possibly due to the multiple sites involved and nuances of their hatching procedure and heterogeneous patient populations. In two sites, patients who underwent assisted hatching with a placebo for immunosuppression/antimicrobial treatment had a significantly lower pregnancy rate than those receiving hatching with corticosteroids and antibiotics possibly supporting their use; however, assisted hatching with corticosteroids and antibiotics did not result in a significantly improved implantation rate over control groups for any subgroup (Primi et al., 2004). More recently, a retrospective cohort study of 876 cycles involving the transfer of an embryo after assisted hatching, with and without corticosteroids and antibiotics. In this study, there was no difference in any clinical outcome between the two groups, causing the authors to conclude regarding their use: “old habits die hard” (Kaye et al., 2017). Further investigation is clearly needed to elucidate whether transfers outcomes of embryos with a breached zona pellucida are improved with immunosuppression and antimicrobial therapy.

Risk of Multiple Gestation Pregnancy/Monozygotic Twinning

From the first publications describing assisted hatching, authors have commented on the observed increase in multiple gestation pregnancies in cases employing this micromanipulation technique. Cohen et al. described a 17% triplet rate compared to a historical 2% triplet rate. While the number of embryos transferred is not described and this could theoretically result from an increased implantation rate, the authors note that monozygotic twinning could result if the inner cell mass divides when passing through the narrow opening in the zona pellucida (Cohen et al., 1990), as was observed in early animal experiments with assisted hatching (Malter and Cohen, 1989). Both a Cochrane meta-analysis of 31 randomized controlled trials and an analysis of 35,503 in vitro fertilization cycles from the Society for Assisted Reproduction Technology (SART) have demonstrated a significantly increased risk of multiple gestation pregnancy after assisted hatching, particularly for monozygotic twins which are associated with increased perinatal morbidity (Schieve et al., 2000; Carney et al., 2012). The Cochrane analysis demonstrated a 38% increase in the OR for multiple gestation pregnancy and monozygotic twins in the SART analysis had an OR 3.2 (95% CI 1.2–8.0) for the use of assisted hatching after controlling for potential confounders. The risks associated with multiple gestation pregnancies, particularly monozygotic multiple gestation are significant. While the absolute risk is low (0.33% monozygotic twin rate in cases with assisted hatching (Schieve et al., 2000)), the uncertain clinical benefit attributed to its use does question engaging any additional risk before undoing any favorable risk–benefit profile. Importantly, no congenital anomalies have been attributed to assisted hatching (Jwa et al., 2015).

Conclusion

Hatching is a critical step for embryo implantation. It is logical that assisting the hatching process for in vitro cultured embryos should improve outcomes—assuming the premise that viable embryos may be trapped in a pathologically thick or impassable zona pellucida. The variety of assisted hatching techniques, nuances of each method’s application, range of embryologist skill and experience, and the diverse indications for use, make it difficult to evaluate inconsistencies in attempts to reproduce favorable outcomes for patients undergoing assisted hatching. For patients with poor prognoses, included older patients with a history of repeated treatment failures, some studies suggest a significant improvement in pregnancy rates; however, larger studies with better

standardization of methods and patients are clearly needed to investigate whether assisted hatching improves the most important outcome, live birth rates.

GENETICS AND EPIGENETICS

Chromosomal Analysis of the Sperm

Lorena Rodrigo Vivó, IGENOMIX, Valencia, Spain

© 2018 Elsevier Inc. All rights reserved.

Glossary

Asthenozoospermia Percentage of motile sperm below 40% (Cooper et al., 2010).

Autosomes The chromosomes identified in humans from number 1 to 22.

Azoospermia Absence of spermatozoa in ejaculate (Cooper et al., 2010).

Criptoospermia Sperm number below 1×10^6 per mL of ejaculate (Cooper et al., 2010).

Gonosomes The two sexual chromosomes identified in humans as X and Y.

Oligozoospermia Sperm number below 15×10^6 per mL of ejaculate (Cooper et al., 2010).

Teratozoospermia Number of sperm with normal shape below 4% (Cooper et al., 2010).

Introduction

Most of the factors associated with male infertility have a genetic component, such as chromosomal abnormalities and genetic defects that affect the reproductive system or spermatogenesis. Errors in synapsis, recombination, and DNA repair processes during male meiosis can generate abnormal segregation of homologous chromosomes at meiosis I or sister chromatids at meiosis II. Several checkpoint mechanisms that regulate the different stages of male meiosis can eliminate defective germ cells to ensure spermatozoa with a normal chromosome content. For this reason, spermatogenesis can be partially arrested in any of the maturation stages, resulting in oligozoospermia, or can be completely arrested, resulting in azoospermia. However, if these control mechanisms are deficient, any of the abnormal cell lines can escape the checkpoints and give rise to spermatozoa with numerical chromosome abnormalities such as aneuploidies or diploidies. Between 2% and 26% of infertile men with normal karyotype exhibit cytogenetic anomalies confined to the germ cell line (Vendrell et al., 1999; Egozcue et al., 2000), which makes sperm chromosome studies particularly relevant.

The first chromosome studies in sperm appeared in 1970 with the use of differential staining of specific chromosome regions. The total aneuploidy rate was estimated at 38%, with 1.4% for sex chromosomes and an average of 2% for autosomes. These rates were considered excessively high and were attributed to the low chromosomal specificity of the technique. In 1978, the development of a technique to fuse sperm with hamster oocytes without zona pellucida, which was standardized in 1982, provided information on the full chromosome content of sperm. However, this technique was complex and laborious, and was limited to the analysis only of spermatozoa capable to fertilize. The mid-1980s gave rise to the development of in situ hybridization techniques using specific DNA probes labeled with radioisotopes. Later, in the 1990s, the use of DNA probes labeled with nonradioactive isotopes allowed the visualization of sperm chromosomes by the fluorescence in situ hybridization (FISH) technique.

Chromosomal Analysis of Sperm by FISH

Using fluorescence DNA probes, FISH technique allows the analysis of numerical chromosome abnormalities of spermatozoa from the ejaculate, the epididymis, and the testis. Due to the nature of the spermatozoa, FISH protocol for sperm analysis requires the following steps.

Sperm Fixation

Before the hybridization, spermatozoa must be fixed maintaining their morphology and allowing permeability to the DNA probes. After centrifugation with sperm washing media, the supernatant containing the seminal plasma is discarded and the pellet with the spermatozoa is fixed with Carnoy solution (3 methanol: 1 glacial acetic acid). The fixed spermatozoa are spread on glass slides avoiding overlapping.

Nucleus Decondensation

Sperm heads have a tightly compacted nucleus due to the presence of disulfide bridges between protamines; this condensation of nuclear chromatin makes it inaccessible to DNA probes. To solve this problem, a pretreatment is performed by incubation with reducing agents and dehydration with ethanol. Reducing agents (e.g., DTT, dithiothreitol) break the disulfide bonds and produce nuclear chromatin decondensation allowing subsequent hybridization with DNA probes.

Denaturation and Hybridization

Double strand DNA denaturation of the sperm and FISH probes is carried out after incubation at high temperature (70°C–74°C). After denaturation, both DNAs are coincubated and hybridized to form a duplex of complementary strands. Hybridization protocols vary according to the type of FISH probe used, requiring different times and temperatures of hybridization (commonly between 4 and 16 h at 37°C–42°C).

FISH on sperm is commonly performed using centromeric, locus specific and subtelomeric fluorescent DNA probes. For segregation studies in structural rearrangements, such as translocations or inversions, specific combinations of these three types of probes are designed for each specific rearrangement. However, in carriers of numerical sex chromosome abnormalities and also in normal karyotype infertile males, the most widely analyzed are chromosomes 13, 18, 21, X and Y by using centromeric and locus specific probes.

Detection

The excess of DNA probes hybridized to unspecific complementary sequences is removed by astringent washes at high temperatures and low saline concentration (e.g., with SSC, saline sodium-citrate). Finally, a counterstain is applied to allow the visualization of the sperm nucleus (e.g., DAPI or DAPI/Antifade).

Signal Visualization and Evaluation

The hybridization signals are visualized using a fluorescent microscope equipped with specific filters for each fluorochrome. The evaluation is performed by counting the number of signals for each fluorochrome present in the nucleus of each spermatozoon. The spermatozoa are haploid cells containing one copy of each autosome and one sex chromosome, X-bearing, or Y-bearing. After the evaluation of the fluorescent signals using the criteria described by Blanco et al. (1996), the spermatozoa can be classified as (see Fig. 1):

Fig. 1 Chromosomal analysis of the sperm by FISH: hybridization of the spermatozoa using a triple FISH with centromeric probes (CEP) for chromosomes 18, X and Y, and dual FISH with locus-specific probes (LSI) for chromosomes 13 and 21; evaluation of FISH signals using epifluorescence microscopy.

- Haploid-normal: when it shows one signal for each of the autosomes evaluated, and one signal for the sex chromosomes (X or Y).
- Disomic: with two signals for one of the chromosomes evaluated, and one signal for the remaining chromosomes evaluated.
- Diploid: with two signals for each of the chromosomes evaluated.

It is recommended to score only spermatozoa with clear hybridization signals, avoiding the analysis of cells with missing signals, as they could represent either nullisomies or hybridization failures.

After evaluation, a sperm sample is classified as abnormal when a significant increase of abnormal sperm (disomies and/or diploidies) is observed compared to the incidence observed in a control population of normozoospermic fertile males.

The total aneuploidy rate in normozoospermic males has been estimated in 6%, with 0.12% mean disomy for autosomes and 0.31% mean disomy for gonosomes (Egozcue et al., 1997). Due to this low aneuploidy rate, for clinical applications a minimal number of 1000 sperm per sample should be scored; nevertheless, this number may be limited in cases of low sperm count such as cryptozoospermic and azoospermic males.

Clinical Indications for Chromosomal Analysis in the Sperm

Currently, FISH in sperm is used in diagnosis protocols of male infertility, allowing the evaluation of the transmission risk of chromosomal defects to the offspring. Discriminating between infertile males with normal and abnormal karyotype, candidates for chromosomal analysis in the sperm would be the following.

Infertile Men With Abnormal Karyotype

Carriers of numerical abnormalities for sex chromosomes

Infertile males with Klinefelter (47,XXY) and 47,XYY syndromes are at risk of low sperm production with poor sperm quality and abnormal chromosome constitution. Blanco et al. (2001) described incidences of 1%–20% of spermatozoa with aneuploidies for the sex chromosomes and 1% diploid sperm in these males.

Carriers of structural chromosome abnormalities

Carriers of balanced chromosomal rearrangements such as Robertsonian or reciprocal translocations and inversions, even with a variable range of alterations during gametogenesis, resulting in normozoospermia, oligozoospermia, or even azoospermia. After spermatogenesis, the spermatozoa can be chromosomally unbalanced in a variable range. The incidence of unbalanced sperm for the chromosomes of the rearrangement is 10%–40% in Robertsonian translocations, 50%–65% in reciprocal translocations, and 1%–55% in inversion carriers (Antón et al., 2007).

Infertile Men With Normal Karyotype

Impaired meiosis in testicular analysis

Low recombination frequency in meiotic pachytene cells has been related to high aneuploidy frequency in sperm, mainly for the sex chromosomes (Ferguson et al., 2007). In fact, a significant correlation has been described between cells with sexual vesicles without recombination sites and sex chromosome disomy in sperm (Sun et al., 2008).

Impaired sperm parameters

Most of the studies performed in oligoasthenozoospermic males describe increased incidences of aneuploid and diploid sperm compared to normozoospermic men (Tempest et al., 2004). The sex chromosomes are the most affected, and the incidence of aneuploidy seems to be directly correlated with the severity of the oligozoospermia, being higher in patients with a sperm concentration lower than 5 million (Rubio et al., 2001; Martin et al., 2003). The same correlation has been observed in testicular sperm from azoospermic patients, mainly in those with nonobstructive azoospermia where up to 42% of the men have an abnormal FISH result (Rodrigo et al., 2011).

However, this correlation is not so clear regarding motility or morphology in sperm. Different studies on isolated asthenozoospermia have found no correlation with meiotic errors even when FISH analysis is performed on motile and nonmotile sperm of the same sample (Zeyneloglu et al., 2000). Nevertheless, a higher correlation with sperm meiotic defects has been observed in cases of isolated severe asthenozoospermia with specific deformities involving sperm flagella (Rives et al., 2005). Regarding isolated teratozoospermia, an increased incidence of aneuploidy and polyploidy seems to be associated with isolated teratozoospermia and specific morphological defects such as large-headed and multiple-tailed spermatozoa (Mateu et al., 2006).

Chemotherapy and radiotherapy treatments

Most chemotherapy or radiotherapy treatments have gonadal toxicity and affect spermatogenesis to a variable degree, depending on the type and duration of treatment. Reports indicate fivefold increases of diploid sperm and sperm with aneuploidies for autosomes and gonosomes after 6 months of treatment compared to their basal level and, in general, these rates decline to basal levels 18–24 months posttreatment (Tempest et al., 2008). Several studies have also described an association between Hodgkin's lymphoma

and impaired spermatogenesis, some of them finding a significant increase in aneuploid sperm before any treatment (Viviani et al., 1991). These data suggest that the emergence of cancer itself induces problems in meiosis.

Clinical history of unknown recurrent pregnancy losses

It has been described that approximately 66% of the abnormal karyotypes from miscarriages have a male origin. Meiotic abnormalities and sperm aneuploidy have been reported in recurrent pregnancy loss (RPL) patients (Ramasamy et al., 2015). Most of the reports describe increases in the incidence of sperm with sex chromosome disomy, and an increase in the diploidy rate was noted in a subset of patients with recurrent miscarriage after ovum donation (Rubio et al., 1999).

Clinical history of repetitive implantation failure

It is thought that oocyte fertilization by a chromosomally abnormal sperm may cause implantation failure. A study carried out in patients with three or more failed ICSI cycles reported that 31.6% of the patients had an increase in spermatozoa with sex chromosome disomy (Rubio et al., 2001). Further, later studies have related an abnormal FISH result in spermatozoa with a decrease in pregnancy and implantation rates in ICSI cycles (Nicolopoulos et al., 2008).

Previous pregnancy with chromosomopathy

Men with chromosomally abnormal offspring of paternal origin, such as Down syndrome (trisomy 21), Klinefelter syndrome (trisomy XXY), and Turner syndrome (monosomy X), have shown incidences of 1%–20% aneuploid sperm, with the altered chromosome affected (Blanco et al., 1998; Eskenazi et al., 2002; Tang et al., 2004).

Impact of Chromosomal Aneuploidies in Sperm

Impact on the Clinical Results

Most published studies related to sperm aneuploidy on infertile men have shown that men with increased frequencies of numerical sperm chromosomal abnormalities have lower pregnancy and implantation rates and higher miscarriage rate after IVF/ICSI than other infertile couples. Several groups have proposed preimplantation genetic testing for aneuploidy (PGT-A) as an alternative to improve the possibility of healthy pregnancies in couples with male infertility (Rubio et al., 2005).

The percentage of abnormal embryos ranged between 43% and 78% in patients with oligozoospermia and azoospermia in which an abnormal sperm FISH or an impaired meiosis were reported. Rodrigo et al. (2013) retrospectively analyzed the reproductive outcome of male factor infertility couples without history of recurrent miscarriage or implantation failure, who carried out sperm FISH analysis for chromosomes 13, 18, 21, X, and Y. IVF/ICSI cycles without embryo chromosomal analysis in couples with abnormal sperm FISH result showed significantly lower embryo transfer rates (64.0% vs. 84.8%), higher mean number of transferred embryos (2.3 ± 0.9 vs. 2.0 ± 0.6), and lower pregnancy (22.9% vs. 30.8%), and implantation rates (12.4% vs. 21.4%) than patients with normal sperm FISH result. However, PGT-A cycles with the embryo analysis of a battery of 9 chromosomes by FISH, showed higher pregnancy (39.7% vs. 28.3%) and implantation rates (33.8% vs. 21.4%) in patients with abnormal sperm FISH result than in patients with normal sperm FISH result. Interestingly, patients with normal sperm FISH analysis had similar clinical results regardless of IVF/ICSI or PGT-A; however, patients with abnormal sperm FISH analysis showed better pregnancy and implantation rates with PGT-A. Embryo aneuploidy screening of the 24 chromosomes in couples with male factor infertility offers even better clinical results, with 83.6% of cycles having at least one euploid embryo to transfer, resulting in a pregnancy rate per transfer of 62.9%, an implantation rate of 54.2% and a take-home baby rate of 50.9% (Rodrigo et al., 2014).

Impact on the Embryo Chromosomal Constitution

In translocation carriers, a correlation has been observed between the percentage of abnormal gametes and the percentage of abnormal embryos (Escudero et al., 2003). In normal karyotype patients, Sánchez-Castro et al. (2009) described a correlation between the percentage of aneuploid sperm and embryos, identifying a 65% of abnormal embryos in patients below 20 millions of sperm count and 3% of total sperm aneuploidy rate, whereas normozoospermic patients with 1.7% of total sperm aneuploidy rate gave rise to lower incidence of 41% of aneuploid embryos.

Additionally, Rodrigo et al. (2010) described a different effect on the embryo according to the type of sperm abnormality. Therefore, sex chromosome aneuploidies in sperm gave rise to aneuploid embryos compatible with life, whereas diploid sperm were more related to triploid embryos that mostly miscarry. In fact, at the offspring level several studies have reported increases in sperm chromosomal abnormalities associated to the chromosomopathies observed in their children. In a study conducted on two fathers of children with Down syndrome of paternal origin, the sperm disomy 21 rates were reported as 0.75% and 0.78% (Blanco et al., 1998). Similar studies in couples with miscarriages or children of carriers of sex chromosome abnormalities (Turner or Klinefelter syndrome) have reported high incidences of sperm aneuploidy for sex chromosomes, ranging from 0.20% to 24.7%.

Clinical Recommendations After Chromosomal Analysis of the Sperm

Taking into consideration the consequences that an increase of numerical chromosome abnormalities in sperm can have on the clinical results, infertility problems and genetic risk for the offspring, if the sperm sample shows an abnormal result, genetic counseling should be advice to the couple. Additionally, several clinical options can be offered, such as prenatal testing when slight increases in aneuploid or diploid sperm; PGT-A in the embryos when moderate-high levels of abnormal sperm; or sperm donation when severe meiosis impairment that results in extremely high increases in abnormal sperm.

Chromosomal Analysis of the Embryo: Preimplantation Genetic Screening

Carmen Rubio, IGENOMIX, Valencia, Spain

© 2018 Elsevier Inc. All rights reserved.

Glossary

Aneuploidy Extra or missing individual chromosome/s.

Blastocyst Stage of preimplantation embryo development at day-5 or 6 after fertilization, with cell differentiation into the trophoctoderm and the inner cell mass.

Euploidy Normal content of chromosomes (23 pairs = 46 chromosomes).

Haploidy A single set of chromosomes ($23 \times 1 = 23$ chromosomes).

Monosomy Missing individual chromosome/s.

Mosaicism Coexisting cell lines with different chromosome constitution within an embryo.

Triploidy Extra set of chromosomes ($23 \times 3 = 69$ chromosomes).

Trisomy Extra individual chromosome/s.

Uniform aneuploidy All cells from an embryo display similar chromosome constitution.

Introduction

Aneuploidy is the most common genetic abnormality in human embryos. It is known that chromosomal abnormalities are implicated in first trimester spontaneous abortions. The incidence of chromosomal abnormalities decreases during the peri-implantation period in such a way that in livebirths, an incidence of 0.6% was observed, a 10-fold increase (6%) was present in stillborn and a 100-fold increase (60%) in spontaneous abortions. This pattern of loss of chromosomal abnormalities from implantation to birth may also operate during preimplantation embryogenesis with a progressive loss of abnormal embryos at specific stages in early development through developmental arrest and degeneration of abnormal embryos (Almeida and Bolton, 1996).

Cytogenetic evaluations in spontaneous abortions, made directly from fetal tissue have revealed an overall incidence of chromosomal abnormalities of 50%–70%. Analysis by chorionic villus sampling has showed higher percentage of chromosomal abnormalities (83%). Most of them are non-inherited numerical abnormalities (parents having a normal karyotype) that appear “de novo”. Only 4.7% of couples with two or more abortions include a carrier of a balanced structural abnormality.

In couples with normal karyotypes, the most common group of abnormalities in spontaneous abortions are autosomal trisomies (75.9%), followed by monosomy X (11.4%), triploidy (6.3%), and tetraploidy (3.8%). Chromosome 16 is the most common trisomy, followed by chromosome 22 and 21. More recently, high incidence of trisomy 15 has been also reported with lower incidence of other important autosomal trisomies, such as trisomy 13 and trisomy 18. It is important to point out that autosomal monosomies have been observed only rarely, despite autosomal monosomies should occur with the same frequencies as trisomies, therefore, they are considered to be responsible of embryo arrest or implantation failures.

The origin of the majority of autosomal trisomies is non-disjunction during maternal meiosis, and they are usually associated with a maternal age effect. Trisomy 16 is incompatible with postnatal survival and non-disjunction studies in spontaneous abortions showed maternal meiotic origin in all the cases, as well as for chromosome 22. Concerning trisomy 21, molecular studies have shown that 8%–9% of the cases were of paternal origin. Among the maternal errors, 75% were attributed to errors in meiosis I and 25% to errors in meiosis II. And about 5% of cases of trisomy 21 were probably due to mitotic nondisjunction (post-zigotic) in the early embryo. The origin of trisomy 18, was determined to be maternal in 91% of the cases, and 9% paternal. Trisomy 13 was the result of maternal errors in 88% of cases and paternal errors in 12% of cases. Monosomy for the X chromosome is the most common single genetic imbalance in first trimester spontaneous abortions. In these cases, the origin of the single X is usually maternal (80%), implying a paternal error exists during meiosis. Maternal sex chromosome mosaicism has been suggested to be responsible for a portion of monosomies 45,X. In 50% of 47,XXY trisomies and in 100% of 47,XYY trisomies, the origin was paternal non-disjunction. And finally, polyploidy occurs following the fertilization of a normal oocyte by more than one spermatozoa or due to meiotic errors during gametogenesis leading to an abnormal diploid oocyte or spermatozoa (Jacobs and Hassold, 1995).

In couples with known risk of aneuploidy, the frequent advice in the past was to offer prenatal diagnosis, either amniocentesis or chorionic villus sampling and more recently non-invasive prenatal testing (NIPT). In these cases, if the fetus is affected, the couple has to decide if they wish to continue with the pregnancy or undergo a termination. Preimplantation genetic diagnosis for aneuploidy screening (PGD-A) offers an alternative for these couples, where the genetic test is performed on the preimplantation embryo. In a PGD-A cycle, the couples should undergo an in vitro fertilization cycle (IVF) to generate embryos in vitro, the embryos are biopsied, and the genetic test is performed on the biopsied cells. PGD-A therefore allows the selection of chromosomally normal embryos to be transferred to the uterus, before the pregnancy is established.

Additionally, reproductive failure in some circumstances can be attributed to the presence of aneuploidy in sperm oocytes and embryos. Therefore, PGD-A can also increase pregnancy rates in infertile couples requiring IVF. This technique has also been called preimplantation genetic screening (PGS) and comprehensive chromosome screening (CCS), among other names.

Incidence of Aneuploidy and Mosaicism in the Preimplantation Embryo

Large datasets from comprehensive aneuploidy screening of preimplantation embryos demonstrate that over half of embryos produced by in vitro fertilization (IVF) are aneuploid (Fransasiak et al., 2014). Aneuploidy rates are higher in oocytes and embryos from women of advanced maternal age, probably stemming from meiotic recombination defects exacerbated by age (Nagaoka et al., 2012). More recently the presence of mosaicism in preimplantation embryos has been also described. Mosaicism refers to the presence of cells with different chromosomal genotypes within a single embryo. It can originate from the first embryo cleavage and can be identified in PGD-A of a blastocyst biopsy with analysis of several cells from the trophectoderm (day-5, day-6, or day-7 embryo biopsy). The first evidence of mosaicism in preimplantation embryos comes from re-analysis studies of aneuploid embryos, and its impact in good quality embryos should not be very high since the analysis of all cells from day-3 embryos or blastocysts showed similar results in all cells in about 97% of the embryos (Mir et al., 2013, 2016; Capalbo et al., 2013).

It is challenging to estimate the real incidence of mosaicism in preimplantation embryos because of technical limitations and because biopsies represent a small percentage of total number of cells of the embryo and will only partially represent the whole blastocyst, depending on the percentage and the distribution of euploid and aneuploid cells in the inner cell mass and trophectoderm. The bioinformatic analysis of sequencing data has difficulty clearly discriminating low-degree mosaicism from experimental noise related to the quality and quantity of the biological samples. There is consensus among most groups to report as mosaic embryos those with >30%–35% of estimated aneuploid cells.

More recently, some authors have proposed the possibility of transferring some types of mosaic embryos, with normal newborns resulting after the transfer into the uterus of mosaic blastocysts (Greco et al., 2015). However, the authors were cautious and state that additional clinical data must be obtained before this approach can be extended. Lately, Fragouli et al. (2017) reported that the transfer of mosaic embryos has significantly poorer clinical outcomes compared to a contemporary control group with the transfer of euploid embryos (ongoing pregnancy of 46.2% vs. 15.4%; $P = 0.003$). The authors concluded that embryo viability is compromised by the presence of aneuploid cells.

Technologies Applied to PGD-A: THE NGS ERA

Several methods allow study of aneuploidies in human embryos—from fluorescence in situ hybridization (FISH) that provides limited information for a few chromosomes, to single nucleotide polymorphism (SNP) arrays, quantitative polymerase chain reaction (qPCR), arrays comparative genomic hybridization (aCGH), and next-generation sequencing (NGS) to analyze all 23 chromosome pairs. The evolution of aneuploidy screening techniques has provided more information about genetic status of the embryo in addition to more reliable and faster results, which enable transfer of euploid embryos during the same cycle.

- **PGD-A version 1.0:** From the 1990s to 2010, FISH was performed on polar bodies or cleavage stage embryos. Numerous retrospective studies claim that the technique works, and thousands of cycles have been conducted worldwide (Munné et al., 1995). FISH assays use fluorescent nucleic acid probes complementary to DNA to visualize regions of interest. However, FISH cannot be performed on all chromosomes simultaneously; therefore, it is targeted to those chromosomes related to spontaneous miscarriages or compatible with live birth, such as chromosomes 15, 16, 17, 18, 21, 22, X, and Y. However, these chromosomes must be assessed over multiple rounds of hybridization, and informativity rates and accuracy of results depend of morphology and integrity of a single nucleus fixed onto a glass slide.
- **PGD-A version 2.0:** New technologies have facilitated the transition from FISH analysis of a limited number of chromosomes to analysis of all 23 chromosome pairs simultaneously in a single cell. Among these technologies, qPCR, SNP arrays, and aCGH have been most widely published to date and have been applied to polar bodies, day-3 and trophectoderm biopsies (Sermon et al., 2016). aCGH technology allows analysis of chromosome DNA copy number variations from an embryo compared to a reference sample. First, DNA from a single blastomere or 4–6 TE cells is amplified via whole genome amplification (WGA). Amplified DNA is then labeled with different fluorescent probes, combined, and hybridized onto a slide containing specific bacterial artificial chromosome (BAC) probes that span the length of chromosomes with ~1 Mb coverage. Chromosome loss or gain is revealed by the color of each spot after hybridization. Fluorescence intensity is detected using a laser scanner and data processing software, which can analyze whole chromosome aneuploidy and sub-chromosomal structural imbalances. SNP arrays also utilize an array setup, although they interrogate specific SNPs in the genome and compare this data to SNP patterns of maternal and paternal partners to arrive at a ploidy call. For qPCR, specific PCR primers amplify a limited section of each chromosome on all 23 chromosome pairs in replicates. By analyzing the relative amount of DNA from each PCR product, a ploidy status can be inferred and assigned to each chromosome.
- **PGD-A 3.0:** This could be considered the latest approach with the possibility to use NGS in a small number of cells from TE biopsies. Decreased cost of genome sequencing has positioned NGS as one of the most promising platforms to study not only

aneuploidies, but also mitochondrial DNA or gene disorders in simultaneous analyses (Fiorentino et al., 2014). For NGS, most extended protocols share the first steps with aCGH protocols, starting with WGA. A barcoding procedure follows this, in which different samples are labeled with unique sequences, so that they later can be mixed, sequenced, and matched to their original patient and embryo. This barcoding process allows 24–96 biopsies to be pooled in a sequencing run, optimizing cost per sequenced embryo. After sequencing, each sequence is aligned with a reference human genome, and copy number variations for whole chromosomes and small deletions/duplications are established using specific software (Vera-Rodríguez et al., 2016).

Clinical Results and Indications of PGD-A

PGD-A was introduced in clinical routine practice to improve pregnancy rates in sub-fertile couples, based on the assumption that high rates of chromosomal aneuploidy—frequently found in cleavage-stage embryos and blastocysts of these couples—were responsible for low pregnancy rates after IVF. Fig. 1, shows aneuploidy rates according to maternal age for blastocyst biopsies with the newest NGS technology. And Fig. 2 shows the percentage of cases with at least one euploid embryo after blastocyst biopsy according to maternal age (Igenomix data obtained from 12,000 cases and > 60,000 biopsied blastocyst).

The main goals for most indications are not only to increase implantation and pregnancy rates, but also to decrease miscarriages, risk of aneuploid offspring, and time to conceive. More recently, cost efficiency per healthy baby at home has also been considered, because with new PGD-A 3.0, blastocyst biopsy and NGS, PGD-A cost is no longer a limitation. There are many factors that contribute to patient-perceived determinants when choosing to accept or decline PGD-A: cost, religion, ethical values, social and family support, provider influences, and past reproductive experience. In light of these results, with the current trend toward single-embryo transfer (SET), it could be argued that failure to investigate chromosomal constitution of the preimplantation embryo to be transferred may raise ethical questions of its own.

Finally, with the gaining popularity of blastocyst biopsy, blastocyst vitrification after trophectoderm biopsy, and deferred transfer, PGD-A fits well into this clinical scheme. A recent study comparing fresh blastocyst transfer and frozen cycles shows improved implantation rate per transferred embryo, although the difference is not significant (75% vs. 67%). However, ongoing pregnancy rates (80% vs. 61%) and live birth rates (77% vs. 59%) are significantly higher with frozen samples compared to fresh transfer. Either transfer strategy can be a reasonable option, but there is a trend toward favoring deferred transfer (Coates et al., 2017). Fig. 3 shows clinical outcomes with PGD-A using blastocyst biopsy with deferred transfer (internal Igenomix data), compared to regular IVF/ICSI (www.sartcorsonline.com/2015).

The following are the most common current indications for PGD-A:

- Advanced maternal age (AMA)

AMA is the most common indication for PGD-A. Maternal age is a major factor in the prevalence of aneuploidy. A study performed in polar body biopsies reported that the rate of missegregation for most clinically relevant aneuploidies (chromosomes 13, 16, and 18) increases from 20% to 60% in women between the ages of 35 and 43 years (Kuliev et al., 2011). Most clinical IVF groups have traditionally considered AMA to be any patient older than 37 years, although recently there is a move to lower the cut-off to 35 years.

Incidence of aneuploidy according to maternal age

Fig. 1 Incidence of aneuploidy in trophectoderm biopsies analyzed in the laboratories of Igenomix.

Chance of transfer according to maternal age

Fig. 2 Percentage of case with at least one euploid blastocyst for transfer. Data from trophoctoderm biopsies analyzed in Igenomix laboratories.

Ongoing pregnancy rate per embryo transfer

Fig. 3 Comparison of clinical pregnancy rates per embryo transference according to maternal age. The comparisons correspond to Igenomix data from trophoctoderm biopsies and the data from cycles without tophectoderm biopsy correspond to Sart data base (www.sartcorsonline.com).

Six randomized controlled trials (RCTs) were published for AMA patients using FISH technology to analyze a limited number of chromosomes. Three indicated that PGD-A offered no benefit (Mastenbroek et al., 2011). These studies were criticized by several authors who argued that the study methodologies had some important pitfalls, including patient inclusion criteria, embryo biopsy procedures, embryo culture conditions, and type of genetic analyses performed. On the other hand, three other studies described lower miscarriage rates and increased delivery rates (Schoolcraft et al., 2009; Rubio et al., 2013, 2017).

Without the ability to screen for aneuploidy, AMA patients with a high percentage of aneuploid embryos may be subjected to multiple unsuccessful embryo transfers for months, some of which may end in distressing miscarriages with the associated medical risks. With the introduction of NGS, PGD-A cost is becoming increasingly affordable and enables embryo chromosome analysis in IVF at a lower cost.

● Recurrent miscarriage (RM)

The definition of RM varies by country, but is generally considered the occurrence of 2–3 consecutive miscarriages with a gestational age up to 14 weeks. For PGD-A, other causes of miscarriage should be discarded before indicating this treatment, with a proper infertility work-up. PGD-A in these couples decreases miscarriage rates to those of general population and therefore increases delivery rates. Among couples suffering from RM, those with previous aneuploid miscarriages and couples with sperm chromosomal abnormalities showed even higher implantation rates and lower miscarriage rates (Rubio et al., 2009).

A retrospective case-control study reports PGD-A implantation rates of 52.63% compared to 19.15% in controls ($P = 0.001$) and almost double ongoing pregnancy rate (61.54% vs. 32.49%; $P = 0.0001$) (Keltz et al., 2013). In addition, a systematic review confirmed that PGD-A may lower miscarriage rates (Musters et al., 2011).

- Repetitive implantation failure (RIF)

RIF is defined as three or more failed IVF attempts or failed IVF treatments after cumulative transfer of > 10 good-quality embryos. RIF-defining criteria are not homogenous, and an exhaustive and comprehensive definition has not yet been reached. Therefore, RIF remains a challenge to clinicians because it can have multiple causes that are still poorly defined. Further, embryo and endometrial factors can play important roles in this condition.

There have been two RCTs published in RIF patients with conflicting results. One of them concluded that there were no significant differences in clinical pregnancy rates with PGD-A-FISH compared to controls (Blockeel et al., 2008). However, the second study that analyzed a few more chromosomes showed a clear trend toward better live birth rates with PGD-A-FISH (47.9% vs. 27.9%) (Rubio et al., 2013). For this indication, despite of age, other combined factors can predict a higher aneuploidy risk, such as low sperm concentration and low ovarian response (Garcia-Herrero et al., 2014).

- Severe male factor infertility (MF)

Couples with impaired sperm parameters have been proposed at increased risk of embryo aneuploidy. Oligozoospermia is associated with significant increases in sex chromosome disomy, chromosome 18 and 21 disomy, and percentage of diploid sperm, particularly in samples with markedly reduced sperm concentrations ($< 5 \times 10^6$ /mL spermatozoa). Such conditions might, in part, explain low implantation and high abortion rates observed in these patients (Rubio et al., 2001). Extreme teratozoospermia (Mateu et al., 2006), testicular sperm from non-obstructive azoospermia (Rodrigo et al., 2011) and from carriers of Y-microdeletions have been also related to increased sperm aneuploidy, mostly for sex chromosomes (Mateu et al., 2010).

Retrospective analysis of trophoctoderm biopsies in severe male infertility have shown significantly greater incidence of sex chromosome abnormalities compared to embryos derived from normal sperm samples. These results highlight severe MF infertility as a possible referral category for PGD-A (Coates et al., 2015).

- Previous trisomic pregnancy (PTP)

Some studies suggest that a PTP is associated with increased risk of another aneuploid conception. In 2009, De Souza and colleagues used register data from Australian population-based birth defects to establish whether the risk of trisomies 13, 18, and 21 (Patau, Edwards, and Down syndrome, respectively) and concluded that women who had had a previous trisomic pregnancy, particularly those <35 years old at the time of pregnancy, appear to have an increased risk of future trisomic pregnancies.

In relation to previous data, a more recent study stated that the incidence of chromosomal abnormalities in preimplantation embryos associated with a previous aneuploid miscarriage was significantly higher in individuals with a previous aneuploid conception (Al-Asmar et al., 2012).

- Good prognosis patients and SET

For patients with a good prognosis, trophoctoderm biopsy using aCGH has high potential to increase overall pregnancy rates in IVF programs and to decrease multiple pregnancies when single elective transfer (SET) is performed. The first RCT comparing blastocyst-stage SET with and without aCGH in good prognosis patients showed an aneuploidy rate of 44.9% among biopsied blastocysts, with a significantly higher clinical pregnancy rate in the PGD-A group (70.9% vs. 45.8%; $P = 0.017$), and no twin pregnancies. This study revealed the limitations of SET when conventional morphology is used alone, even in patients without an increased risk for aneuploidy, because the aCGH group implanted with greater efficiency and yielded a lower miscarriage rate than those without aCGH (Yang et al., 2012).

Key-Aspects in the Current Practice

- *Female age.* As described along the text, this is the main contributing factor to aneuploidy. However, once an euploid embryo is transferred, pregnancy rates remain high up to 43–44 years of age.
- *Male age.* There has been no clear association of paternal age with the incidence of aneuploidy or clinical outcome, however with the new technologies and the possibility to test for mosaicism and small deletions/duplications, this factor would need to be revisited.
- *Hormonal stimulation.* There is current agreement that despite the percentage of aneuploid embryos could increase with higher hormonal dosage and response, the absolute number of euploid embryos in a single cycle would not be impaired. In addition, with the possibility of blastocyst vitrification after biopsy, the potential negative impact of stimulation on the endometrium could be overcome.
- *Ovarian reserve.* This factor is not associated to aneuploidy, the percentage of aneuploid embryos is not related to ovarian reserve, but has a clear impact in the probability of obtaining an euploid embryo for transfer.
- *Sperm concentration.* As previously mentioned, when this value decrease below 2–5 millions of sperm/mL indicates an impairment of male meiosis with higher risk of sperm aneuploidy.
- *Day of biopsy.* The current approach is trophoctoderm biopsy on day-5/6 blastocyst, obtaining between 4 and 8 cells for a more accurate genetic analysis, including mosaicism detection.

- *Technology for chromosomal analysis.* The aim is to analyze all 23 pairs of chromosomes, with the proper technology to detect uniform aneuploidy and mosaicism and partial aneuploidies (small duplications/deletions).
- *Day of transfer.* Blastocyst vitrification after trophectoderm biopsy is becoming frequent, with a deferred transfer of a thawed blastocyst in a non-stimulated cycle. In PGD-A is scheduled with a fresh transfer, the most common approach is day-5 biopsy with the transfer on the morning of day-6. This latest approach has the limitation that only embryos developing to blastocyst stage on day-5 could be analyzed.

Glossary

Blastocyst An embryo that has developed for five to 7 days after fertilization and has two distinct cell types and a central cavity filled with fluid (blastocoel).

Chromosomal aneuploidy A condition in which a cell has an incorrect number of chromosomes.

Haplotyping A combination of alleles (for different genes) that are located closely together on the same chromosome and that tend to be inherited together.

Human Leucocyte Antigen (HLA) A gene complex encoding the major histocompatibility complex (MHC) proteins which are responsible for the regulation of the immune system in humans.

Karyomapping A genome-wide linkage based approach to assess disease status in embryos.

Monogenic Involving or controlled by a single gene.

Next generation sequencing (NGS) A catch-all term for high-throughput technologies enabling massively parallel or deep sequencing which has revolutionized genomic research.

Preimplantation genetic diagnosis (PGD) A technique using in vitro fertilization (IVF) to ensure that an embryo does not inherit a known genetic defect from either parent.

Preimplantation genetic screening (PGS) A technique used as part of an in vitro fertilization cycle which identifies chromosomal aneuploidy with the aim of selecting only chromosomally normal embryos to improve IVF outcomes.

Whole genome amplification (WGA) A catch-all term to describe any technology designed to amplify a limited genomic DNA sample so as to generate a new sample that is indistinguishable from the original but with a higher DNA concentration.

Background

For couples with known risk of transmitting a specific genetic condition to their offspring, preimplantation genetic diagnosis (PGD) is often viewed as an alternative to prenatal diagnosis because it avoids the difficult decision regarding termination of an affected pregnancy following a positive prenatal test. In addition, given the increasing age at which women are having children and the concomitant problems associate with delayed childbearing, PGD can also be considered as a means to increase the likelihood of, and reduce the time to, having an unaffected pregnancy, by selecting from multiple embryos. In brief, oocytes and/or preimplantation embryos obtained following in vitro fertilization (IVF) are analyzed and only those embryos free of the disorder under study are transferred to the uterus to achieve pregnancy.

The first successful application of PGD in humans involved sexing of embryos by polymerase chain reaction (PCR) to avoid males affected with an X-linked disorder. Gender was determined in single blastomeres by PCR using primers for amplifying Y-chromosome-specific DNA sequences and embryos identified as female were selectively transferred to the uterus ([Handyside et al., 1990](#)). Later, successful PGD was reported for cystic fibrosis, based on the amplification of a DNA fragment containing the causative mutation and its detection by fragment analysis ([Handyside et al., 1992](#)). Since then, PGD for single gene disorders has evolved to incorporate the detection of several mutations and multiple linked markers to improve both the accuracy and reliability of testing ([Fiorentino et al., 2006](#); [Harton et al., 2011a](#)). Despite the tiny amount of diagnostic material available and the ever-present dual threats of allelic dropout and contamination, technological advances coupled with best practice and rigorous quality assurance measures now deliver reliable results with an extremely low incidence of misdiagnosis ([Wilton et al., 2009](#); [De Rycke et al., 2017](#)).

Today, PGD indications have been expanded and PGD is performed in laboratories worldwide. The precise number of PGD cycles that have been performed to date can only be estimated. The European Society for Human Reproduction and Embryology (ESHRE) PGD consortium has collected data for PGD cycles since 1999, with over 12,000 PGD cycles performed with several thousand healthy children born. The most recent report described 3445 cycles for single-gene disorders, including human leucocyte antigen (HLA) typing ([De Rycke et al., 2017](#)). Although the ESHRE data represent only a partial record of the PGD cases conducted worldwide, they are indicative of the general trend in the field.

PGD requires a multidisciplinary approach with deep collaboration between the IVF clinic and the genetic laboratory, which can either be colocated within the same facility or, more frequently, remote. In this latter situation, an effective transportation and logistics operation must be in place; IVF treatment (controlled ovarian stimulation, oocyte retrieval and in vitro fertilization, embryo culture and embryo transfer) is carried out in the IVF clinic, and only the biopsied embryonic samples are transported to the reference laboratory conducting the PGD analysis.

Regarding clinical results of PGD, the last data collection carried out for the ESHRE consortium showed that 79% of PGD cycles resulted in an embryo transfer. The clinical pregnancy rate obtained for the cycles was 25% per oocyte retrieval and 31% per embryo transfer, giving an overall implantation rate of 23%. Finally, the delivery rate was 20% per oocyte retrieval and 26% per embryo transfer and the miscarriage rate was 11% (De Rycke et al., 2017). However, these clinical results should be considered with caution as the cycles were conducted in 2011–12, there may be significant differences in the clinical results between the different IVF centers within the consortium and some of the best centers may not submit data to the consortium.

PGD has become a routine, state-funded and regulated treatment in some countries providing a humane, effective and realistic option for at-risk families. Where PGD is regulated, it is generally limited to serious conditions with a high likelihood of transmission. For adult onset disorders, HLA matching, previously untested disorders or cases with borderline severity, it is sometimes necessary to apply to a specific body for approval. Elsewhere, it is not universally recognized or accepted for various religious, ethical and legal reasons (Soini, 2007).

This article will focus on PGD for single gene disorders, as the analysis of chromosomal rearrangements and generalized aneuploidy will be dealt with elsewhere in this book.

Indications for PGD

PGD is recommended when couples are at risk of transmitting a known genetic abnormality to their children and, therefore, the indications are similar to conventional prenatal diagnosis. PGD has mainly been used to diagnose and prevent well-defined autosomal recessive, autosomal dominant or X-linked single-gene disorders. The conditions for which PGD has been applied increase annually and, in theory, almost all single gene disorders that have been characterized can be diagnosed in the embryo. Other uses for PGD include gender selection, compatible HLA typing (aiming for a 'saviour sibling'), the identification of hereditary cancers with variable penetrance (e.g., BRCA 1, 2 status) and late onset genetic diseases; all of which have been considered controversial. While not exhaustive, the list of over 400 conditions in the UK approved for PGD by the fertility regulator (HFEA) is interesting, as all have had to pass a legal test for seriousness and likelihood of transmission (Human Fertilisation and Embryology Authority, 2017).

Single Gene Disorders

According to recent ESHRE PGD consortium data, the most common indications are for cystic fibrosis, spinal muscular atrophy and some hemoglobinopathies (De Rycke et al., 2015); all autosomal recessive disorders which involve the presence of two mutated copies from each healthy carrier parent.

For autosomal dominant conditions, one mutated copy of the gene is enough for a person to be affected. Myotonic dystrophy type 1, neurofibromatosis and Huntington's disease are the most frequently requested indications (De Rycke et al., 2015). In some cases, an affected person inherits the condition from an affected parent. In others, the condition may result from a new (de-novo) mutation in the gene and occurs in people with no family history of the disorder. When the patient has a de-novo mutation it is necessary to identify the molecular change causing the disease. Once the mutation has been characterized, this change must be analyzed directly in the embryo.

X-linked recessive disorders are mainly transmitted by healthy carrier mothers to their sons. In these cases, affected males will have no risk of affected offspring; all daughters will be obligate carriers, but no sons will be affected. PGD for X-linked disorders is mainly performed for Duchenne's muscular dystrophy, hemophilia and fragile-X syndrome (De Rycke et al., 2015). Although initially, sexing with FISH was widely applied for X-linked disorders and only female embryos selected for transfer, specific diagnosis of the molecular defect has important advantages and has replaced FISH. First, it facilitates the identification and subsequent transfer of those healthy male embryos that by FISH diagnosis would be discarded. Second, female carriers may be identified that can be excluded from transfer or not, according to patient wishes or center policy. This is significant for those X-linked dominant conditions (e.g., fragile-X syndrome) where carrier females can manifest disease symptoms.

Cancer Predisposition and Late-Onset Diseases

PGD is also offered to those couples where one partner carries a mutation predisposing to cancer or other late-onset disease. For cancer predisposition syndromes that are not fully penetrant and for which some form of therapeutic measures may be available, prenatal diagnosis and termination of pregnancy remain controversial and PGD appears as an attractive option, preventing the difficult decision of termination of an established pregnancy. In contrast, PGD for diseases that will not develop until adulthood, or for mutations that only confer a heightened risk, raises issues of how to balance the possible benefits of PGD for the future child against the risks of PGD and IVF for the patient. Despite these ethical concerns, the number of PGD cycles reported for these types of conditions is increasing, and the procedure has been performed for a number of diseases, including the common syndromes of genetic predisposition to colon and breast cancer (De Rycke et al., 2015, 2017; Rechitsky et al., 2002).

For some adult-onset conditions (e.g., Huntington's disease), patients with a family history of the disorder do not wish to know their genetic status in advance, but want to ensure that their children do not have the mutation. Unlike prenatal diagnosis, PGD for

Huntington's disease allows the status of the "potential" mutation carrier to be blinded, either by nondisclosure or the less ethically troublesome exclusion tests (Sermon et al., 2002). In the former, the mutation is analyzed but the results are not revealed to the patient. This approach has several practical and ethical problems including the requirement to withhold details of the IVF cycle to avoid any potential clues regarding the patient's carrier status. Moreover, a mock transfer might be necessary if no embryos are suitable for transfer so that the patients do not suspect they are carriers. In the exclusion test, those embryos inheriting the haplotype coming from the affected grandparent are ruled out for the transfer with the unfortunate consequence that, even if the patient is not a carrier, some unaffected embryos could be rejected.

HLA Matching

Another controversial but well-established indication is HLA matching in which PGD is used to help couples conceive a child (with or without a specific genetic risk themselves) who may donate compatible cord blood or hematopoietic stem cells for transplantation to save an affected sibling (Verlinsky et al., 2001), as HLA-identical donors are frequently unavailable. Hematopoietic stem cell transplantation (HSCT) from an HLA-identical donor is the best therapeutic option for genetic diseases affecting the hematopoietic and/or immune system in children (e.g., β -thalassemia, Fanconi anemia), and can also be an effective therapeutic option for acquired diseases (e.g., leukemia, acquired medullary aplasia).

PGD to select an embryo free of an inherited condition and HLA-matched to an existing affected child was first applied for Fanconi anemia in 2001 (Verlinsky et al., 2001) and has since been performed for a number of different hematopoietic diseases.

Where PGD/HLA testing is used to select embryos that are both HLA matched and free from specific disease, the chance of an embryo being both unaffected and a match is only 18.75% in the case of autosomal recessive conditions (e.g., beta-thalassemia), thus there are fewer embryos available for transfer and consequently poorer IVF success rates. Furthermore, many patients requesting preimplantation HLA typing are of advanced reproductive age, with corresponding reduced success, such that many patients require two or more attempts before delivering an HLA identical offspring. Counseling for such patients must include expectation management regarding realistic success rates, timelines and the possible requirement for bone marrow stem cells if cord blood is insufficient (Kahraman et al., 2014).

Diagnostic Methods

PCR and Fragment Analysis

A direct multiplex PCR approach using targeted primers designed specifically for the mutation of interest combined with primers for closely linked STR markers has been traditionally the gold standard to perform PGD for monogenic disorders. During pre-PGD work up, the analysis of polymorphic markers in DNA samples from patients and potentially informative relatives identifies which alleles are expected in the embryos, and the specific marker alleles which cosegregate with the mutation. This combined linkage and mutation detection approach improves accuracy, minimizing potential errors caused by undetected allele drop out (ADO) and/or contamination (Fiorentino et al., 2003). ADO refers to the amplification failure (or extreme preferential nonamplification) of one of the two alleles, making a heterozygous locus appear homozygous, and potentially leading to misdiagnosis.

Genotyping of the amplified products can be performed using many different strategies including amplification refractory mutation system, restriction enzyme digestion and real-time PCR, with minisequencing the most common method for point mutation detection (Fiorentino et al., 2003). In the minisequencing technique, a primer extension reaction is performed, allowing rapid and accurate detection of point mutations. The minisequencing primer is designed to anneal one base before the target site, and it can only be elongated with one specific dideoxynucleotide. The four different dideoxynucleotides are labeled with different fluorochromes, and the products analyzed on an automated DNA sequencing system.

The use of multiplex PCR for linkage markers alone (so-called preimplantation genetic haplotyping or PGH) has become widespread in PGD for monogenic disorders (Renwick et al., 2010) and HLA typing. The main advantage is that such protocols can be used for several couples, independent of the mutation they carry, thus saving time and resources in pre-PGD workups. A genome-wide linkage approach, karyomapping (Handyside et al., 2010), further expands on this concept using commercially available microarrays to provide an off-the-shelf accurate and reproducible semiautomated solution to PGD following a whole genome amplification step (see below).

Whole Genome Amplification (WGA)

The creation of robust, accurate multiplex protocols requires careful design, optimization and validation before clinical use, with a large investment of time and resources needed. The widespread adoption of whole genome amplification (WGA) has proved to be a practical and efficient alternative to direct testing to facilitate single cell testing for PGD and many commercially available products are now available (Huang et al., 2015). In general, WGA amplifies the entire 6 picograms of the single cell genome producing microgram quantities of DNA—enough for multiple downstream applications including standard PCR assays for haplotyping and the direct analysis of mutations in case of monogenic diseases. This can avoid the need to optimize multiplex PCR protocols on single

cells (Renwick et al., 2010; Handyside et al., 2010). Moreover, WGA allows combined PGD for single gene disorder or HLA typing with array comparative genomic hybridization (aCGH) or Next Generation Sequencing (NGS) for the detection of chromosomal imbalances using the same sample with the aim of improving clinical PGD results (Rechitsky et al., 2015). Finally, WGA facilitates repeat testing of samples for use in proficiency testing, validation or in the case of run failure.

Despite the large quantities of amplified DNA generated, WGA methods yield relatively high ADO rates overall from single cells (Huang et al., 2015). This problem can be circumvented with the application of enough linked markers to avoid misdiagnosis (e.g., with karyomapping) and/or reduced with the use of trophoctoderm biopsies instead of single cells because the former provides multiple cells in the biopsy sample, which is known to result in lower ADO rates.

Karyomapping

Historically, the growth of PGD has been limited by the need to develop individual protocols for different diseases and families. However, karyomapping is a universal, robust, off-the-shelf approach to PGD which uses a high-density single nucleotide polymorphism (SNP) array to accurately identify parental DNA haplotypes in embryonic samples. By genotyping the parents at several hundred thousand SNP sites throughout the genome, a set of highly informative SNP markers are identified for each of the four parental chromosomes (Handyside et al., 2010). The phase of the alleles for each informative SNP locus along each chromosome and linkage of the risk alleles with the parental chromosomes can then be established by reference to the genotype of a relative of known disease status (either affected or unaffected). The parental origin of each chromosome in the embryo is then ascertained by comparison with the genotype of the reference. A similar approach has been developed called haplarithmisis, but it is not yet commercially available (Zamani Esteki et al., 2015). Karyomapping's main advantage compared with the gold standard mutation plus linkage analysis method (described above) is that it is applicable to almost any familial single gene disorder, or any combination of loci, within the chromosome regions covered by informative SNP loci, eliminating the need to develop patient- or disease-specific tests (Handyside et al., 2010; Renwick et al., 2010). The main challenges of the karyomapping approach are that diagnosis is difficult when insufficient informative SNP markers are available (e.g., in some telomeric genes and in highly consanguineous families), or when pseudogenes are involved. Moreover, it cannot be used alone for de novo mutation cases or when other tested family members are not available to provide samples or are uninformative owing to recombination. In such cases, direct mutation testing from at least one embryo is necessary to establish phase i.e., identify on which chromosome the mutation is present (Konstantinidis et al., 2015).

However, this approach has several limitations (as described above), which need to be overcome as more carrier screening tests are performed that identify cocarriage of mutations in the same gene among couples with no family history or affected children—the historic source of referrals for PGD. At present, karyomapping is not commercially validated for aneuploidy screening and does not readily detect mitotic trisomies nor simple copy number variation. Nonetheless, use of karyomapping, for the most part, represents a significant advance over the current gold standard for PGD and will be a powerful tool to investigate parental origin and phase of origin of meiotic chromosome errors.

Next Generation Sequencing

Next generation sequencing (NGS) provides high-throughput and base pair resolution data, providing the analysis of multiple genetic loci and samples from different couples simultaneously. Moreover, NGS, as with karyomapping, allows the combined evaluation of aneuploidy and single-gene disorders from the same biopsy using a single platform.

A number of studies demonstrate the possibility of using NGS to test single cells for PGD (Treff et al., 2013; Sermon et al., 2016). One used DNA from a trophoctoderm biopsy with NGS that was consistent with two conventional methodologies of PGD (Treff et al., 2013). However, the major concern relating to NGS technology is that an insufficient sequencing depth may result in false positive or failure to identify a mutation (false negative) due to the presence of sequencing artifacts and ADO, respectively. Moreover, NGS has technical limitations in testing for dynamic mutations. Further studies are needed to evaluate this technology before its routine clinical use in PGD, although given its penetration in other diagnostic arenas NGS for PGD appears inevitable.

Combined PGD and Chromosomal Screening

Extensive evidence has revealed a high incidence of chromosomal abnormalities in human embryos obtained by assisted reproduction techniques leading to miscarriages and implantation failures (Sermon et al., 2016) and this is dealt with in more detail elsewhere in this book.

Couples presenting for PGD to avoid transmission of single gene disorders are not without these same problems despite the fact that they are often categorized as “fertile.” Indeed, many PGD patients may be of advanced age because they have already had affected children or pregnancies. For this reason, they can also benefit from the simultaneous analysis of the disease and the presence of aneuploidies, selecting for transfer those PGD “unaffected” and simultaneously euploid embryos. Indeed, reported PGD results have never been particularly high when reported together. The genetic basis of the disorder under test can affect the success

rates (as, for example, fewer embryos are available for transfer when testing a dominant condition versus a recessive one) and maternal age (as with routine IVF) is the single biggest predictor of a successful outcome. Since the main cause of IVF failure in advanced maternal age is chromosomal abnormality, it is rational to consider selection of only euploid embryos after PGD as a way to improve pregnancy rates per transfer and reduce miscarriage rates.

Several studies have shown significant improvement in rates of pregnancy and live births following testing for aneuploidy in patients undergoing IVF for infertility (reviewed in [Sermon et al., 2016](#)). The use of the WGA product provides a straightforward solution for performing any required test in the same biopsy material, allowing the simultaneous analysis of PGD and aneuploidy screening. Using this approach the first systematic study of PGD combined with the aneuploidy screening was published, demonstrating an increase in the pregnancy rate from 45.4% in the conventional PGD to 68.5% with combined aneuploidy screening and 3-fold miscarried reduction (5.5% vs. 15%) ([Rechitsky et al., 2015](#)).

Currently, it is possible to determine both monogenic diagnosis (plus HLA haplotyping) and aneuploidy detection by PGD using two different techniques on the same WGA product ([Rechitsky et al., 2015](#)). For this reason, a single assay using the same platform to detect simultaneously both chromosomal and monogenic disorders is desirable. Since both karyomapping and haplarithmism define unique sets of SNP markers for each of the four parental chromosomes, they represent such a method ([Handyside et al., 2010](#); [Zamani Esteki et al., 2015](#)), by allowing accurate identification of the region of interest containing the mutation and simultaneous high-resolution molecular cytogenetic analysis. Meiotic trisomies can be identified by the presence of both haplotypes from one parent in segments of the chromosome, resulting from the inheritance of two chromosomes with different patterns of recombination, in combination with a single haplotype from the other parent. Moreover, monosomies or deletions can be identified by the absence of one of the parental haplotypes ([Handyside et al., 2010](#); [Zamani Esteki et al., 2015](#); [Konstantinidis et al., 2015](#)). Both haplarithmism and karyomapping represent significant advances toward a universal PGD test (combining detection of specific single gene disorders and chromosomal aneuploidy), but both need further validation for aneuploidy detection against current gold standard methods.

Challenges, Limitations and Barriers to Access

Today, not all people who wish to have PGD can do so. This is mainly due to a lack of funding (PGD requires costly IVF and technologically advanced testing), limited access to treatment (not all IVF laboratories have biopsy skills or links with a suitable diagnostic laboratory) or in some cases legal restrictions, for example in Germany and Norway ([Soini, 2007](#)). It is essential that the disorder that is intended to be diagnosed has a comprehensive and accurate genetic characterization to at least identify the gene responsible for the condition. Some conditions, including autism, diabetes and heart disease, where the causes are either unidentified, polygenic or there are imprecise risk factors, are not suitable for PGD.

As PGD involves both an IVF procedure and a selection procedure based on genetic testing, it is important to estimate the number of unaffected embryos expected for transfer prior to starting the procedure. This number depends on the embryo quality and the theoretical risk according to the genetic disorder (e.g., recessive, dominant, sex-linked). The embryo's potential to implant depends mainly on the woman's age and the presence of additional viability factors. Chromosome aneuploidy is the major cause of IVF failure and miscarriage. To benefit patients, sufficient embryos should be analyzed to obtain unaffected embryos for transfer. Recent advances in vitrification procedures have made it feasible to batch oocytes or embryos to reach a minimum number of embryos for analysis. [Table 1](#) shows the rates of transferable embryos considering the inheritance patterns and the potential presence of aneuploidies (Igenomix, unpublished data).

One final significant point regarding PGD concerns patient and clinician expectation. PGD provides no guarantee of a completely healthy baby. Instead, PGD minimizes the risk for the disease for which the couple has a high risk of transmitting to their offspring. However, there remains a small risk of misdiagnosis due to the existence of mosaicism or technical limitations, and therefore couples should always be offered the possibility of prenatal diagnosis to confirm results. Moreover, couples may assume that a normal healthy child following successful PGD for a specific disorder is guaranteed, forgetting that a more cryptic disorder or

Table 1 Rates of transferable embryos considering the inheritance patterns and the potential presence of aneuploidies

<i>Indication</i>	<i>Unaffected embryos</i>	<i>PGS normal embryos^a</i>	<i>Transferable embryos</i>

X-linked dominant	1/2	1/2	1/4
HLA matching	1/4	1/2	1/8
HLA + AD	1/8	1/2	1/16
HLA + AR	3/16	1/2	3/32
HLA + X-linked	3/16	1/2	3/32

^a50% of blastocysts are expected to be PGS abnormal on average (Igenomix, unpublished data).

a de-novo mutation or abnormality which was not tested for may be present. Indeed, even with a genome-wide linkage based approach such as karyomapping, no other genes or mutations even within the same gene are routinely analyzed if there was no indication to do so. Furthermore, if chromosomes are not analyzed, an aneuploid but genetically unaffected embryo may be transferred. The entire procedure should always be explained in detail by a suitably qualified genetics professional before treatment to ensure that couples are informed about the potential risks and limitations (Harton et al., 2011b).

Future Perspectives for PGD

The rapid rise of lower cost, high-throughput and accurate next generation sequencing technology combined with the temporal separation of the biopsy and diagnostic procedures via improved embryo vitrification techniques has improved patient access to PGD, while providing more time for diagnosis and genetic counseling. The accuracy and reliability of PGD is improved when performing a multicellular trophectoderm biopsy from a blastocyst and this has become the gold standard approach. Improvements in noninvasive assessment of chromosomal aneuploidy in blastocoel fluid and spent culture medium could herald a new era in which no biopsy is necessary even for single gene disorders (Xu et al., 2016). Further technical improvements enabling the simultaneous analysis of single gene disorders and chromosome aneuploidy from the same sample may reduce costs to patients and improve implantation and rates of healthy live births whilst reducing miscarriage, time to pregnancy and patient dropout rates. The rapid uptake of pan-ethnic expanded preconception carrier screening for couples with no family history of specific genetic disease following professional guidelines, improved access and reduced cost, as well as government funding for PGD in many countries is certain to increase the number of PGD cases further. The increased demand for PGD should also drive standardization of best practice (Schoolcraft et al., 2017), and an evolution of existing guidelines (Harton et al., 2011a) to ensure that we learn from the challenges and mistakes of the past. Areas for focus include embryo selection for biopsy (a more inclusive approach), biopsy safety (safe laser use), sample preparation and identification (built in molecular assessment of contamination and embryo identification). Finally, recent advances in genome editing in embryos (Ma et al., 2017) bring ever closer the possibility of shifting the focus of PGD from “selection” to “correction” by repairing genetic defects in embryos, thereby “curing” previously incurable disorders including those with polygenic inheritance. Whatever the future holds for PGD, a robust, well-planned ethical and legal framework will continue to be important to ensure patient safety and public confidence.

Conclusions

PGD can be used to screen embryos for almost any kind of genetic disorder in which the genetic cause is characterized, thus the number of indications and total number of PGD cases increases year on year. With improving technologies, best practice guidelines and the adoption of external quality assessment programmes and laboratory accreditation (Harper et al., 2010), PGD analysis has reached a high level of accuracy, enabling multiple diagnoses from the same sample. Diagnosis of a monogenic disease can be combined with HLA typing and/or detection of chromosomal abnormalities to improve reproductive outcomes. The current strategy of blastocyst biopsy and vitrification, followed by later transfer of unaffected embryos in a thaw cycle, has superseded the cleavage stage biopsy and fresh transfer approach and will be further embedded as the gold standard for PGD following robust clinical trial data demonstrating the benefits of frozen-thaw versus fresh embryo transfer cycles. Despite all the advances made in PGD, one fundamental principle still remains true: successful PGD requires a platform of successful IVF.

Mitochondria and Embryo Viability

Mitochondria

Mitochondria play an important role in the generation of energy in eukaryotic cells, using the process of oxidative phosphorylation to derive energy (ATP) from carbohydrates and fatty acids. It is also important to remember that mitochondria it is not only energy factory as a central metabolic organelle, as a raw material factory, execute critical biochemical functions for the synthesis of anabolic precursor for fundamental cellular components, including amino acids, fatty acids, and nucleotides. Mitochondria contain their own genome, which encodes tRNAs, rRNAs, and some mitochondrial proteins. Ranging in size from 0.5 to 1.0 μm in diameter, these organelles have a double-membrane system consisting of inner and outer membranes separated by an intermembrane space. The outer mitochondrial membrane encloses the matrix (internal space) and contains a large number of proteins as transporters allowing the importation of mitochondrial proteins that encoded in the nucleus and synthesized in the cytoplasm, in addition multiple transporters that import and export numerous substrates and products for and from metabolic activity. The inner mitochondrial membrane, which is folded into structures (cristae) that increase the surface area, is less permeable, blocking the movement of ions and other small molecules allowing the generation of a membrane potential for energy production (Fig. 1).

Origin of Mitochondria in Eukaryotes

Eukaryotes are genetic chimeras. They have genes that they inherited vertically from their archaeobacterially associated host. Eukaryotes possess genes that they inherited vertically from the endosymbiont. Typical mitochondria harbor up to more than a 1000 proteins that are encoded in the nucleus. Throughout the course of eukaryotes origin, many genes were transferred from the genome of the mitochondrial endosymbiont to the genome (nuclear) of the host. This kind of endosymbiotic gene transfer is nothing unusual; endosymbiosis very often entails gene transfers from the endosymbiont to the host. It happened during the origin of plastids too, and it is still ongoing in our own genome: Mitochondrial DNA constantly escapes from the organelle and becomes integrated as copies into nuclear DNA. The vast majority of mitochondrial proteins are encoded by nuclear genes, and many of these are endosymbiotic acquisitions from the mitochondrial ancestor.

Similar to eukaryotes themselves, mitochondria have arisen only once in all of evolution. The top evidence for the single origin of mitochondria comes from a preserved set of genes preserved in the mitochondrial DNA across all known eukaryotic groups including plants. In the case of hydrogenosomes (which usually lack DNA) and mitosomes (which so far always lack DNA), the strongest evidence for their common ancestry with mitochondria is twofold.

Fig. 1 Diagram of a mitochondrion. The different components of mitochondria are represented.

New Data Are Continuously Improving Our Views Regarding Mitochondrial Evolution

The autogenous hypothesis is less supported suggests that mitochondria were born by splitting off from a portion of DNA in the nucleus of the eukaryotic cell (Gray, 2012). The endosymbiotic hypothesis, proposed by Lynn Margulis, is the most official, it established the idea that mitochondria evolved from free-living bacteria via symbiosis within a eukaryotic host cell (Margulis, 1970).

The oldest eukaryotic microfossils date back 1.45 billion years. This date matches up to a time when the oceans were mostly anoxic because of the workings of marine H₂S-producing bacteria. Eukaryotes appeared and branched out in an environment where anoxia was common. The mitochondrial genome appears to have a monophyletic origin from α -Proteobacteria with Rickettsiales and several *Rickettsia*-like endosymbionts identified as the α -Proteobacterial order most closely related to mitochondria (Gray, 2012) (Fig. 2).

It is possible that the host that acquired the mitochondrion was a prokaryote. This is linked to the idea that the ancestral mitochondrion was a facultative anaerobe, perhaps similar in physiology to modern Rhodobacterales (Martin and Mentel, 2010). Although, existing data suggest that the mitochondrial genome originated from the eubacterial, not the archaeal, domain of life (specifically α -Proteobacterial). In fact, *Rickettsia prowazekii*, the etiologic agent of epidemic typhus, transmitted in the feces of lice, stands out as the most genetically similar to mitochondria.

Mitochondrial Is Not Only an ATP Factory

The top implicit mitochondrial role include ATP production by oxidative phosphorylation, β -oxidation of fatty acids, and metabolism of amino acids and lipids. In addition, mitochondria have different and complex functions, like participating in multiple cell signaling cascades. Proteins such as GTPases, kinases, and phosphatases are implicated in bi-directional communication connecting the mitochondria and the rest of the cell, contributing in the regulation of metabolism, cell-cycle control, embryonic development, antiviral responses, and cell death (McBride et al., 2006). Furthermore, there is an important role in the regulation of numerous proteins in response to calcium signaling. Mitochondria respond to calcium both as a calcium buffer and as the propagator of intracellular calcium waves during muscle contraction and synaptic vesicle release (McBride et al., 2006). Another example of the incorporation of mitochondria in signaling pathways is its fundamental role in the apoptotic cascade and cell death (Ott et al., 2007); indeed, mitochondrial fragmentation and cristae remodeling are essential steps for “cytochrome *c*” release and cell death (McBride et al., 2006).

Further, mitochondrial dysfunction is associated to genomic instability and abnormal RNA and DNA synthesis, since multiple enzymes responsible for metabolism of cytosolic ribonucleotides and deoxyribonucleotides are existing in mitochondria. For instance, serine, a major resource of one-carbon anabolic units, is necessary for the synthesis of glycine, thymidylate, methionine, epigenetic methylation reactions, and purine synthesis. Serine, is converted to glycine, and a methyl group is transferred from serine to tetrahydrofolate (THF), yielding glycine and 5,10-methylene-THF (Desler et al., 2010). In the mitochondria, 5,10-methylene-THF is transformed into formate in a series of enzymatic exchanges beginning with conversion into 5-methyl-THF and afterward into 10-formyl-THF. Cytosolic 10-formyl-THF is a fundamental one-carbon-unit donor for the de novo synthesis of purine

Fig. 2 Time line from the origin to present-day. The principal invasions giving rise to proto-mitochondrion are showed (Ga, billion years ago).

nucleotides (Desler et al., 2010). This route reveals the importance of mitochondria in DNA/RNA synthesis. In addition, mutations affecting the activity of the electron transport chain can lead to a damaging effect on cytosolic dNTP levels, originating instability in the nuclear genome (Desler et al., 2010).

In addition, reactive oxygen species (ROS) are reactive molecules that comprise various chemical species like superoxide anion, hydroxyl radical, and hydrogen peroxide. About 1%–2% of the molecular oxygen consumed in the course of physiological respiration is transformed into superoxide radicals (Ott et al., 2007). Mitochondrial ROS are produced in the electron transport chain through one-electron carriers interact straightly with mitochondrial proteins, lipids, and DNA. This results a plethora of oxidative modifications as lipid peroxidation, protein oxidation, and mitochondrial DNA (mtDNA) mutations. Without a doubt, as the majority of ROS are products of mitochondrial respiration, mitochondria are the major targets for their damaging.

Oxidative DNA injury affects replication and transcription of mtDNA. This inhibits mitochondrial function, which increases production of ROS. Therefore evolution have improved mitochondria defense system to detoxify ROS and repair ROS-induced damage. Numerous studies have suggested that mtDNA is more vulnerable to oxidative damage (Cui et al., 2012). Therefore, oxidative stress plays an important role in aging, and the modulation of this system directly affects the responsiveness of cells to go through.

Mitochondrial DNA

mtDNA is a circular DNA molecule of 16.5 Kb that is situated in the matrix. Its genetic code differs to some extent from the universal one, in that AUA codes for methionine and not isoleucine and UGA codes for tryptophan and not STOP. Also, mtDNA has no introns. In humans, 100–10,000 separate copies of mtDNA are usually present per cell and is dependent of mitochondrial activity. For example, power demanding tissues such as cardiac and skeletal muscle contain between 2000 and 10,000 thousands of copies of mtDNA per cell, with an average mtDNA copy number per mitochondrion between 1000 and 10,000 copies. Less energy-demanding tissues, like the lungs, have a typical amount between 200 and 3000 copies per cell and 50 and 300 per mitochondrion. In oocytes mitochondrial content has been estimated between 100 and 640 thousands, and it is assumed in general that each mitochondrion holds one or two genomes (reviewed by Van Blerkom, 2009) (Fig. 3A).

The mtDNA has a regulatory sequence, involved in replication and transcription, known as the D-loop. It also encodes 2 rRNAs (12S and 16S), 22 tRNAs, and 13 mRNAs, Sequence and organization of the human mitochondrial genome. There are also some proteins that are encoded by mtDNA and synthesized in the mitochondria. These proteins are fundamental subunits of the electron transport complexes of the electron transport chain (ETC): one subunit of complex III, seven subunits of complex I, three subunits of complex, and two subunits of complex V. If mtDNA genes are mutated, the functions of the ETC are affected; mutations in the nuclear genes encoding mitochondrial proteins can affect multiple mitochondrial functions (Fig. 3B). It is important to emphasize that mtDNA mutates faster than nuclear DNA due to its location near the ETC and the absence of protective histones. As a result, mtDNA is more exposed to the harmful effects of ROS.

Inheritance of Mitochondrial DNA and Bottleneck Selection

mtDNA is maternally inherited (Stewart and Larsson, 2014). Even though a zygote receives both maternal and paternal mtDNA at fertilization, the paternal mtDNA is specially targeted for elimination and removed from the cytoplasm of the zygote during very early embryogenesis (Sato and Sato, 2012).

The amount of mitochondria present in a metaphase II oocyte (Van Blerkom, 2009) correspond to only a small portion of the maternal mtDNA pool due to a genetic bottleneck that takes place in the course of oogenesis. In the primordial germ cells there is a great population of mtDNA that represents the maternal mtDNA pool. This is the starting point of the genetic bottleneck. At some stage in development of the germline, the maternal mitochondrial pool is subsampled to a quite small number resulting in only a small percentage of mtDNA being represent in the mature egg. In this way, the variety of mtDNA is restricted in each oocyte, and homoplasmy is promoted. Therefore, within a cohort of oocytes there are differences for the reason that the maternal mtDNA is arbitrarily segregated; in fact, in mtDNA diseases the level of mutant mtDNA differs in oocytes from the same patient (Marchington et al., 1998). Subsequent to the bottleneck, during oocyte maturation, there is an augment in mitochondrial content and mtDNA copy number (Fig. 4).

Mitochondrial Biogenesis and mtDNA Replication

mtDNA replication is mediated by a number of nuclear-encoded transcription and replication factors. These factors, together with mtDNA, form the mitochondrial nucleoid, which is in charge for the packaging, transcription, and replication of the mitochondrial genome. The nucleoid proteins include mitochondrial-specific polymerase gamma (which contains two subunits, POLGA and POLGB), mitochondrial transcription factor A (TFAM), mitochondrial RNA polymerase (mtRNA pol), mitochondrial transcription factor B (TFBM), helicase (Twinkle), key transcriptions factors (TFB1M, TFB2M), mitochondrial single-stranded DNA-binding protein (mtSSB), and mTERF. All of these are placed in the central region of the nucleoid; in contrast, ATAD3 is arranged

Fig. 3 (A) Scheme of mitochondrial DNA (mtDNA). mtDNA is composed by a D-loop (regulatory sequence) and 37 genes (22 tRNAs, 2 rRNAs, and 13 proteins). (B) The inner membrane contains the respiratory chain which is composed by five complexes. The 13 proteins encoded by mtDNA are distributed along the respiratory chain: seven in complex I, one in complex III, three in complex IV and two in complex V. Nuclear genome encodes Complex II entirely. An electrochemical gradient is generated across the inner membrane by H^+ pumps (Complexes I, III and IV). Finally, Complex V (ATP-synthase) pumps H^+ to the matrix and ATP is produced.

Fig. 4 Diagram of mtDNA copy number variation. During oogenesis, the copy number of mtDNA is reduced due to a genetic bottleneck. Subsequently, an amplification of the remaining fraction of mtDNA occurs. From the stage of mature oocyte, no further mtDNA replication befalls until blastocyst stage. Therefore, the number of mtDNA is being reduced during the cleavage division. mtDNA replication resumes at blastocyst stage, and it is thought that it starts before in the trophectoderm than in the inner cell mass.

Table 1 Principal proteins involved in mitochondrial DNA replication

Nucleoid protein	Function
POLGA	mtDNA polymerase, catalytic subunit
mTERF	Termination of transcription
mtSSB	Stabilizes mtDNA and stimulates twinkle activity
Twinkle	mtDNA unwinding
ATAD3	Backbone to the nucleoid
POLGB	mtDNA polymerase, accessory subunit. Forms an heterotrimer 2:1 with POLGA
mtRNA pol	Transcription of mtDNA, that generates RNA primer to mtDNA replication
TFAM	Transcription factor, starts replication
TFBM	Forms heterodimer with RNA polymerase, allowing specific transcription initiation

peripherally and acts as the backbone of the nucleoid (reviewed by St. John). **Table 1** summarizes the functions of mitochondrial nucleoid components.

TFAM starts replication; its binding to mtDNA induces structural modifications that result in exposure of the initiation region. Next, mtRNA pol synthesizes an RNA that becomes a primer used by POLGA to begin mtDNA replication. This process is supported by POLGB, which stabilizes POLGA and increases efficiency, and mtSSB and Twinkle, which mediate mtDNA unwinding. The mitochondrial genome replication differs from the organelle's replication and is controlled by signals modulated by cellular energetic demand, as results as previously explained copies of mtDNA are dependent of mitochondrial activity.

Studies in mouse models point out that, in standard situations, no further mtDNA replication takes place between the mtDNA amplification in the fertilized oocyte and the blastocyst stage: the total quantity of mtDNA remains constant from the one-cell oocyte through the early blastocyst stage (Piko and Taylor, 1987). Therefore, during cleavage divisions, the amount of mtDNA remains stable and mtDNA is apparently reduced with each cell division. As a result, the number of mtDNA molecules per cell is constantly diluted. At the blastocyst stage mtDNA replication is resumed (Thundathil et al., 2005); it is supposed to begin first in the trophectoderm (TE), then in the inner cell mass (ICM). In a pig model, mitochondrial-specific polymerase is increased in the outer edges of embryos at the morula stage, in the area of cells that are expected become TE. However, it is stable in the inner embryo, representing future ICM cells. Quantitative examination of ATP generation in mouse embryos also supports the idea that approximately 80% of ATP is generated in TE (Houghton, 2006).

Mitochondria a Shape Shifter Organelle

During oocyte growth and maturation, mitochondria are predominantly spherical to oval with a diameter $\leq 1 \mu\text{m}$ and are characterized by an increasingly dense matrix (Motta et al., 2000; Sathananthan and Trounson, 2000). Their appearance makes them seem inactive; in spite of this, some are generating ATP by oxidative phosphorylation (Van Blerkom, 2009). The organization remains unchanged until the eight-cell stage, when a reduction in matrix density happens gradually. During blastocyst differentiation, expansion, and hatching, mitochondria turn into progressively more elongated, show a less dense matrix, and have more abundant cristae, a clear sign of augmented metabolic activity (Motta et al., 2000; Sathananthan and Trounson, 2000).

Mitochondrial Function in the Early Embryo

Oxidative Stress and Early Embryo Development

As previously described, mitochondria generate ROS in the course of oxidative phosphorylation. These ROS produce oxidative stress if they are not controlled. Oxidative stress in an embryo is an inductor of apoptosis and embryo fragmentation during early development. Reasonably, then, the embryonic DNA should be protected from mitochondrial ROS, and this likely the evolutionary mechanism that explains why the early embryo presents little mitochondrial activity.

Mitochondria have a decisive role in apoptosis during early development; pro-apoptotic factors such as cytochrome *c* and apoptosis-inducing factor are out from the intermembrane space into the cytosol and activate caspase activation. In mouse zygotes go through in vitro culture, treatment with hydrogen peroxide (H_2O_2) induces cell death. Mitochondria are clearly involved in oxidative stress-induced cell death by liberation of mitochondrial pro-apoptotic factors. Oxidative stress is associated with the fragmentation rate of human embryos. H_2O_2 production is considerably higher in fragmented embryos compared to nonfragmented ones, and is connected with apoptosis and DNA fragmentation (Yang et al., 1998). However, the in vivo environment differs from the in vitro environment by the presence of defense mechanisms against ROS (Yang et al., 1998; Guerin et al., 2001). Antioxidants are present in the cumulus cells, (Bedaiwy et al., 2004) follicular fluid, ovarian tissue, fallopian tubes, and endometrium. They protect the oocyte and embryo by preventing ROS formation, capturing ROS, and supporting DNA repair (Agarwal et al., 2005). A study in which ROS levels were measured on the first day of in vitro culture after in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI) showed that lower pregnancy rates are related to high ROS levels. Increased ROS levels are associated with low blastocyst, fertilization and cleavage rates, and high embryonic fragmentation only in ICSI cycles. This can be explained because in conventional IVF but not ICSI-only, cumulus cells are there and they may have antioxidant activity (Agarwal et al., 2005).

Mitochondrial Ca^{2+} Signaling and Fertilization

Fertilization of egg by sperm leads to metaphase II oocyte activation, resumption, and conclusion of meiosis, extrusion of the second polar body, and pronuclear formation. This activation produces zona pellucida and plasma membrane remodeling, cortical granule exocytosis and initiation of maternal mRNA translation. Intracellular Ca^{2+} signaling has a clear role during fertilization. Sperm-egg fusion conducts to an increase in cytosolic Ca^{2+} levels, going after a series of oscillations in Ca^{2+} levels (Armant, 2015). In the mouse, sperm-triggered Ca^{2+} waves created in the fertilized egg stimulate mitochondrial oxidative phosphorylation. In addition, mitochondrial oxidative phosphorylation is essential to maintain those Ca^{2+} oscillations. When a mouse egg is cultured in a medium devoid of the substrates required by mitochondria, it can be fertilized but the Ca^{2+} waves are repressed.

As fertilization involves ATP, it could be considered that ATP levels will decline during the process. Nevertheless, after fertilization in the mouse, no decline in ATP levels is observed. This denotes that energy supplies match the energy demand. Ca^{2+} signaling created by the entrance of the spermatozoa to the oocyte activates ATP production in mitochondria; thus, the energy required for this process is supplied (Armant, 2015), and small activity of oxidative phosphorylation are preserved when energy is not needed (Ramalho-Santos et al., 2009). In summary, the Ca^{2+} increase created by fertilization acts as a connection between cell energy necessities and energy production, that is, mitochondria. This activates the production of energy essential to undergo successive developmental stages, and when no energy is needed small levels of oxidative phosphorylation are preserved. In turn, mitochondria are fundamental to maintaining Ca^{2+} oscillations that are required to complete meiosis and begin embryo development.

Mitochondria Is a Stress Sensor

Mitochondria are capable to sense internal or environmental changes, such as diet and poisonous substances. Mitochondria indicate stress by membrane depolarization, changes in adenine nucleotide levels, ROS production, Ca^{2+} fluxes, permeability transition pore opening, and secretion of proteins/peptides. They also control bioenergetic, thermogenic, oxidative, and/or apoptotic responses so they can restore homeostasis (Fig. 5).

Severe exposure to stress intermediaries is linked with increase in mitochondrial biogenesis and changes of activity in the respiratory chain complexes, controlled production of ROS, thermogenesis, and apoptosis. In a chronic stress condition, the injure

Fig. 5 Blastomere energy production. The energy required in the early embryo development can be produced by two possible mechanisms using different substrates: glycolysis (glucose) and oxidative phosphorylation (pyruvate). During the first stages of development the energy is produced in the mitochondria by oxidative phosphorylation (OXPHOS), at blastocyst stage there is a shift to ATP generation by glycolysis.

can surpass mitochondrial responses and produce abnormal mitochondrial biogenesis, respiratory chain dysfunction, decreased ATP production, increased ROS generation, lipid peroxidation, mitochondrial and nuclear DNA damage, and increased cell apoptosis (Manoli et al., 2007) (Fig. 6).

The “quiet embryo hypothesis” proposes that, by decreasing oxygen consumption (quiet metabolism) from the zygote to morula stage, the embryo confines the formation of ROS and there is less injury to the genome, transcriptome, and proteome. In contrast, the more “noisy” the embryo, the bigger the level of injury and activated demand for nutrients and energy (Fragouli et al., 2015; Leese, 2012). The embryo is likely reliant on energy accumulation throughout oocyte maturation, and only in a stress circumstances (reduced metabolic fuel) does the cellular machinery act in response to increase mtDNA copy number in an attempt to produce more energy. Thus, mitochondrial dysfunction is associated with mitochondrial hyperproliferation (Fragouli et al., 2015; Meldrum et al., 2016).

Mitochondrial biogenesis is mainly activated by increased energetic stress. It requires the control of several processes such as mtDNA synthesis, import and synthesis of nuclear-encoded proteins, and the assembly of proteins from nuclear and mitochondrial DNA. This regulation requires a set of nuclear transcription factors and coactivators, including PPAR coactivator 1a (PGC-1a) as the principal member. A drop in ATP activates energetic demands increasing the cellular adenosine monophosphate (AMP)/ATP ratio, which is sensed by AMP-activated protein kinase (AMPK). AMPK p activates PGC-1a, inducing mitochondria maturation increasing mtDNA copy number and cristae density (Meldrum et al., 2016).

An increase in mtDNA copy number in embryos would be indicative of metabolic stress. This stress could be connected to essential factors during oocyte maturation or could be in response to impaired respiratory capacities due to mtDNA mutations (Meldrum et al., 2016; Diez-Juan et al., 2015).

It has been demonstrated in human embryos that in response to impaired respiratory capacities due to mtDNA mutations, resulted in a reduced mtDNA copy number in germinal vesicles and MI metaphase oocytes gradual rise in mtDNA copy number from the germinal vesicle to the blastocyst stage (Monnot et al., 2013). Thus, initial oocyte mtDNA copy number could be independent of final values if there are factors affecting energetic or metabolic demands of the preimplantation embryo.

Mitochondria DNA Copy Number in Embryonic Implantation and Development

An important contributor to embryo viability is an adequate energy supply. This energy is provided by the accumulated mitochondria present in the oocyte, and only in cases of reduced metabolic fuel is there an increased mtDNA copy number (Meldrum et al., 2016; Diez-Juan et al., 2015).

Fig. 6 The mitochondrial response to acute or chronic stress. Acute stress increases the energy cells demands. Thus, an increase of mitochondrial biogenesis and the enzymatic activity of selected subunits of the respiratory chain complexes is produced. Chronic stress to the mitochondrial homeostasis can exceed mitochondrial reserves provoking a decrease in mitochondrial biogenesis and ATP production, respiratory chain dysfunction and an increase in ROS generation and mitochondrial DNA damage.

Because mtDNA content remains stable during the first days of embryonic development, as shown in the mouse, the total amount of mtDNA must be split among cells during embryo division. On day six of development, each embryo cell should contain very few copies of mtDNA (Diez-Juan et al., 2015; Cummins, 1998) until mtDNA replication resumes after implantation. Disrupting the mouse gene for mitochondrial transcription factor A (low mitochondrial number in oocytes) does not affect fertilization or early embryonic development because the embryo continues with implantation and gastrulation. However, these embryos die by embryonic day (E) 10.5, indicating that the replication of mitochondria is not initiated until well after implantation (Van Blerkom, 2009; Meldrum et al., 2016; Larsson et al., 1998). The ability of embryos to implant suggests that oxidative phosphorylation is not required at this stage, or that the maternal contribution of functional mitochondria is sufficient.

New research has demonstrated that high mtDNA copy number in euploid embryos is indicative of lower embryo viability in terms of implantation potential (Diez-Juan et al., 2015), and aneuploid blastocysts contain significantly greater amounts of mtDNA. Further, increases in mtDNA content are associated with embryo loss (Fragouli et al., 2015). Manoli et al. (2007) assessed day 3 and day 5 embryos. The analysis of blastocysts revealed that blastocysts from older women had a higher mtDNA copy number, aneuploid blastocysts had a higher mtDNA copy number (independent of age), and euploid blastocysts that failed to implant had a significantly higher mtDNA copy number; and pregnancy did not occur when mtDNA copy number was above a relative threshold. Similar study at the same time, by Diez-Juan et al. (2015) assessed samples obtained from 205 cleavage stage embryos and 65 blastocysts. Similarly to the first study, a single blastomere from cleavage stage embryos and 5–10 blastomeres from blastocysts were tested for euploidy and mtDNA copy number, using aCGH and qPCR, respectively Diez-Juan et al. (2015) found that mtDNA copy number negatively correlated with implantation potential of euploid embryos, not only for blastocysts but also for cleavage stage embryos.

Final Remarks

Optimal maturation of the oocyte rest on its biological environment and governs embryo competence, since the embryonic genome is not activated until the cleavage stage and new mitochondria are not formed until blastulation. Environmental milieu like aging, oxidative stress, obesity, smoking, alcohol, and psychologic stress affects mitochondrial function and energy production affecting

ovarian reserve, chromosome segregation, and embryo competence. Mitochondrial metabolic stress can result in an abnormal compensatory increase in mitochondrial DNA, which can be assessed in biopsied blastomeres of trophectoderm as a predictive biomarker of implantation failure. Enhancing oocyte competence is a key intervention that promises to reduce the number of euploid embryos failing to produce viable deliveries, interventions that increases endogenous energy reserve and/or production should be a step forward to improve embryonic implantation and development in natural and clinical human reproduction.

Glossary

Biomarker A characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention.

Endometrial fluid Body fluid inside the uterine cavity that contains the molecules secreted from the endometrial glands to the uterine lumen. This fluid can be obtained by aspiration of the cavity by transcervically introduction of a thin and flexible catheter.

Endometrial receptivity Period within the menstrual cycle in which the endometrium acquires a functional status able to promote and support blastocyst implantation.

Endometrial receptivity analysis Is a personalized genetic test, developed and patented in 2009 by IGENOMIX, to diagnose the endometrial receptivity state in the window of implantation.

Genome-wide association studies Studies to identify DNA markers of variants across the genome related to a trait or disease. This kind of study has been lately proven useful for the prevention, diagnosis or treatment of several diseases.

NEXT-generation sequencing Modern technology that allow the sequencing of DNA and RNA much more quickly and cheaply than the previously used Sanger sequencing, revolutionizing the study of genomics and molecular biology.

“Omics” sciences General term for a broad discipline of science and engineering that analyze different molecules or processes at a large scale as well as the interactions of biological information objects in various “omes”: genome, transcriptome, proteome, lipidome, secretome, etc.

Personalized embryo transfer Novel therapeutic strategy used in patients with displaced window of implantation in which the embryo is transferred guided by the endometrial timing.

Pinopodes Smooth protrusions that arise from the apical surface of the luminal epithelium cells of the endometrium.

Recurrent implantation failure Clinical condition that prevents the final success of assisted reproduction. It is defined as three or more IVF cycles in which one or two morphologically high-grade embryos were transferred.

Window of implantation Period during the menstrual cycle in which the endometrium is ready to receive the embryo and start the pregnancy. This occurs around days 19–21 in each menstrual cycle of a fertile woman.

WOI Window of implantation

Introduction

Endometrial receptivity is a physiological state in which the endometrium acquires an adhesive phenotype permitting embryo implantation, the initial step of pregnancy. Three main events are essential for the onset of a successful pregnancy: an euploid blastocyst ready to implant, a receptive endometrium, and correct embryo–maternal crosstalk (Cha et al., 2013). This allows the embryo to appose, attach, penetrate, and invade the endometrial barrier and gain access to essential nutrients required for proper growth and development. However, impaired synchronization between the embryo and endometrium will lead to implantation failure. The acquisition of endometrial receptivity occurs during a specific period of time known as the window of implantation (WOI) in the mid-secretory phase of the menstrual cycle (Hertig et al., 1956; Navot et al., 1991), but this WOI varies between patients. Thus, diagnosing endometrial receptivity plays a pivotal role in assisted reproductive technologies (ART) to avoid implantation failure and improve pregnancy outcomes.

Acquisition of Endometrial Receptivity

The endometrium is a hormonally regulated organ, and its receptive phenotype is achieved by activation of specific receptors for steroid ovarian hormones. During the follicular phase of the menstrual cycle, estrogen levels rise and stimulate endometrial cell proliferation. Then, after ovulation, the corpus luteum begins secreting progesterone promoting the physiological and molecular changes that prepare the endometrium to receive the developing embryo and maintain the pregnancy.

These changes affect different cell types in the endometrium, that is, the luminal and glandular epithelia and the stromal compartment. During the WOI, luminal epithelial cells undergo morphological remodeling leading to loss of polarity; apical microvilli known as pinopodes appear on the luminal surface; and adhesive molecules, such as integrins and mucins, and certain cytokines are upregulated. At the same time, the glandular epithelial cells increase in size and secrete the required factors to nurture the implanting embryo. Then, endometrial stromal cells begin differentiating in a process referred to as decidualization, which is characterized by acquisition of a rounded phenotype, increased storage of nutrients, accumulation of uterine natural killer cells, and vascular reorganization surrounding the site at which implantation is to occur (Evans et al., 2016). If the embryo does not implant, the decidualized endometrium is shed leading to menstruation and a new functional endometrial layer is regenerated in the next menstrual cycle (Fig. 1).

Technical Assessment of Endometrial Receptivity

Because a receptive endometrium is mandatory for the initiation of pregnancy, several strategies have been proposed to identify the WOI (Aghajanova et al., 2008).

Morphological Evaluation of Endometrial Receptivity

Histology and immunohistochemistry

The morphological analysis of endometrial receptivity started with the histological dating of Noyes, based on features of the different endometrial compartments across the menstrual cycle (Noyes et al., 1950). These criteria have been used as a gold standard over six decades to assess the endometrial receptivity status. Nonetheless, subsequent retrospective, prospective, and randomized studies have questioned the accuracy and functional relevance of this method, leading to its discontinuation (see Miravet-Valenciano et al., 2015).

Immunohistochemical staining has been used since the 1990s to complement the analysis of endometrial dating by Noyes criteria. For this purpose, several markers of endometrial receptivity have been used to assess the abundance and localization of adhesion proteins, cell cycle progression of endometrial cells, or the regulation of immune cells in endometrial specimens. Because endometrial receptivity involves an adhesive phenotype, the abnormal expression of adhesion proteins has been studied as potential markers of uterine receptivity. In this regard, alpha-1, alpha-4, and beta-3 integrins are examined in women with unexplained infertility (Lessey et al., 1995) and constitute the basis of *E-tegrity* a clinical diagnosis test of endometrial receptivity (<http://www.etegritytest.com>). However, the association of beta-3 integrin with endometriosis (Lessey et al., 1994) is the main limitation of this test and may result in confounding results. In addition, the expression and subcellular localization of two cell-cycle proteins, cyclin E and cyclin-dependent kinase inhibitor p27, involved in endometrial cell mitosis have been used to determine the endometrial receptivity in donor ovum recipients (Kliman et al., 2006) and helped establish the rationale for the endometrial function test® (EFT®) (<http://klimanlabs.yale.edu/infertility/eft/>). Endometrial receptivity has also been analyzed by immunohistochemical detection of immune cells involved in maternal adaptation to the semiallogenic developing embryo, especially uterine natural killer (uNK) cells. Recently, it has been reported that high abundance of cytotoxic CD16(+) cells or the NKp46(+):CD56(+) ratio can be used as a marker of increased endometrial inflammation that correlates with implantation failure or pregnancy loss. However, the prognostic value of measuring total uNK cells or CD56(+) cells in endometrial specimens remains uncertain (Giuliani et al., 2014).

Nature Reviews | Endocrinology

Fig. 1 Acquisition of endometrial receptivity. (1) Before receptivity, the luminal epithelium is nonadhesive to the embryo. (2) The glandular epithelium becomes secretory. (3) Immune cells proliferate and migrate to the endometrium. (4) The luminal epithelial cells undergo modifications for the acquisition of the receptive phenotype: loss of polarization and increased surface adhesion molecules. (5) At initiation of receptivity, pinopodes appear on the surface of luminal cells. (6) The correct embryo–maternal communication is essential for implantation. (7) Decidualization of the endometrial stromal cells starts in perivascular regions. (8) Fibroblastic stromal cells acquire a rounded phenotype and secrete molecules that facilitates decidualization spread. Scanning electron microscopy

Scanning electron microscopy (SEM) can distinguish the two types of cells, that is, the secretory and ciliated cells, present in the endometrial epithelium at the ultrastructural level. Ciliated cell morphology does not change significantly during the menstrual cycle. In contrast, the secretory cells undergo hormone-dependent morphological changes, including the protrusion of pinopodes on their apical surface during the WOI (Martel et al., 1991). For this reason, pinopodes have been proposed as morphological markers of endometrial receptivity. However, due to the technical complexity, price, and turnaround time of SEM, its use is limited to research. Moreover, the timing of pinopode formation, their function, and their value for diagnosing endometrial receptivity are controversial (Quinn and Casper, 2008).

Ultrasound

Ultrasound evaluation of the uterine cavity is a general practice in reproductive medicine. A triple-layered pattern and an endometrial thickness of 7–14 mm, measured by abdominal ultrasound, have been considered optimal for implantation, but a meta-analysis comparing ART outcomes in patients with endometrial thickness above or below 7 mm did not show differences between these two groups, indicating that endometrial thickness cannot itself be considered a receptive marker (Kasius et al., 2014).

Three-dimensional ultrasound has allowed the measurement of endometrial volume in correlation with endometrial receptivity reporting that an endometrial volume higher than 2 mL at the time of embryo transfer is a positive predictive variable of ART success.

Finally, the quantification of endometrial and subendometrial blood flow using color power Doppler sonography has been related to receptivity, showing that abundant endometrial flow correlates with better implantation and clinical pregnancy rates while undetectable blood flow is associated with implantation failure (Wang et al., 2010).

However, contradictory results have been found by other researchers concluding that there is no predictive value for these techniques.

Molecular Evaluation of Endometrial Receptivity

Biochemical markers

The endometrium proliferates in response to estrogen, and differentiation is dependent on progesterone secretion from ovarian follicles. Then, the preimplantation embryo enters the uterine cavity driven by L-selectin signaling. There, the antiadhesion molecule mucin prevents the blastocyst from attaching to the endometrium before reaching an implantation site, to which the embryo is attracted by increased levels of specific cytokines and chemokines. Finally, adhesion molecules help the blastocyst to implant.

Different molecules have been proposed as potential biomarkers of endometrial receptivity due to roles in the above processes as well as their differential abundance during the WOI compared to other phases of the cycle. These differential molecules can be the cause or the consequence of the morphological features of endometrial receptivity and involve: adhesion molecules, cytokines, chemokines, and growth factors (Table 1). However, single biomarkers do not often offer enough specificity to discriminate the correct endometrial receptivity period. Because of this, none of the aforementioned molecular markers have been successfully used as a sole marker for clinical management (Aghajanova et al., 2008).

High throughput techniques

Technological advances promise to improve the prediction of the WOI. Thus, molecular evaluation of endometrial receptivity has recently focused on complete profiles of molecules rather than specific biomarkers. This is possible thanks to the so-called “omics” sciences that have demonstrated a more accurate prediction of endometrial receptivity than those provided by morphological or visual analyses. In fact, a clinical transcriptomic array has displaced histological dating as the gold standard of endometrial receptivity in current clinical practice.

Proteomics

Proteomic approaches reflect cellular functions through the identification of differential levels of detectable proteins. Following the development of mass spectrometry, studies profiling protein expression in endometrial samples have improved our understanding

Table 1 Biochemical markers of endometrial receptivity

Type of molecule	Biomarker	Role/abundance in endometrial receptivity
Adhesion	L-selectin ligands	Expressed in luminal and glandular epithelium to receive L-selectin expressed by the trophectoderm cells of the blastocyst prior to implantation
	$\alpha 1\beta 1$ - and $\alpha 1\beta 4$ -integrins	Differentially overexpressed in receptive stage
	$\alpha V\beta 3$ -integrin	Specifically expressed during the window of implantation. It is associated with increased implantation and pregnancy outcomes
	Mucin	Antiadhesive protein expressed in the luminal epithelium to prevent attachment of embryo outside the contact sites
Cytokines	Cadherins	Involve in calcium-dependent cell-to-cell interaction
	IL-6	Overexpressed during the mid-secretory phase of the menstrual cycle in the luminal epithelium and recognized by IL-6 receptors expressed in the embryo
	LIF	Induces different transcriptional factors and signaling pathways leading to cell polarity changes, angiogenesis and stromal cell decidualization
Chemokines	IL-1	Expressed in epithelial and stromal cells during the WOI. Enhances the expression of $\alpha V\beta 3$ -integrin
	IL-8	Acts as a chemoattractant in luminal epithelium for endometrial receptivity
	MCP-1	Involved in immunomodulation and inflammation in the embryo–endometrial interphase
	RANTES	Mainly located in stromal cells during the WOI. RANTES receptors are expressed in the preimplantation embryo
Growth factors	HB-EGF	Induces expression of $\alpha V\beta 3$ -integrin in luminal epithelium. Influences glandular epithelium secretions
Others	Glycodelin A	Induced by progesterone. Modulates immune response to prevent rejection from the mother to the embryo to allow successful implantation
	Osteopontin	Ligand for $\alpha V\beta 3$ -integrin
	Calcitonin	Increases intracellular calcium to modulate cytoskeleton reorganization, epithelial cells remodeling and polarity
	HOXA 10	Transcription factor that regulates $\alpha V\beta 3$ -integrin expression

Reviewed in Achache, H. and Revel, A. (2006). Endometrial receptivity markers, the journey to successful embryo implantation. *Human Reproduction Update* 12(6), 731–746 and Miravet-Valenciano, J. A., Rincon-Bertolin, A., Vilella, F., and Simon, C. (2015). Understanding and improving endometrial receptivity. *Current Opinion in Obstetrics and Gynecology*, 27(3), 187–192.

of the biological processes underlying implantation. The first proteomic study comparing the proliferative and secretory endometrium identified five differentially expressed proteins, but the utility of those proteins in endometrial receptivity has not yet been evaluated (DeSouza et al., 2005). A later study comparing the proteomic profile of prereceptive (LH+2) versus receptive (LH+7) endometrial samples using differential in-gel electrophoresis and mass spectrometry identified 35 differentially expressed proteins (12 upregulated and 23 downregulated) in the receptive phase. Interestingly, two proteins associated with the cytoskeleton, Annexin A2 and Stathmin 1, showed consistent differential expression (Dominguez et al., 2009). Annexin A2 promotes fibrinolytic activity on the surface of vascular endothelial cells by assembling plasminogen and tissue plasminogen activator and by accelerating the generation of plasmin; Stathmin acts as a regulator of microtubule dynamics during cell-cycle progression. This is consistent with the required remodeling of the epithelial cells to achieve the receptive phenotype. The functional analysis of these proteins on a refractory endometrium (induced by the insertion of an intrauterine device) indicated that the labeling pattern for these proteins was similar to that present in the prereceptive endometrium, suggesting that Annexin A2 and Stathmin 1 are functionally involved in endometrial receptivity.

Lipidomics

The large-scale study of lipids secreted from the endometrial cells into the uterine cavity has also been used to find molecular markers of endometrial receptivity. Mass spectrometry has revealed that endocannabinoids, lysophosphatidic acid, and prostaglandins are the most important lipids in the uterus at the time of embryo implantation, meaning that the endometrium presents a specific pattern of lipids during the WOI. Specifically, the secretion of prostaglandins PGE2 and PGF2 α into the endometrial fluid is significantly higher during the mid-secretory phase of the menstrual cycle in healthy asymptomatic women (Vilella et al., 2013), suggesting that these two lipids could predict receptivity. Twenty-four hours before embryo transfer, the endometrial fluid of patients who became pregnant in their current IVF cycle contained higher levels of PGE2 and PGF2 α than endometrial fluid from patients who did not (Vilella et al., 2013).

Transcriptomics

The transcriptome, created by analyzing mRNA content, reflects the genes that are actively expressed at any given time in a specific cell population. It provides expression profiles that can accurately predict endometrial functionality as well as diagnostic or prognostic criteria. Genes involved in metabolism, glandular secretion, cell differentiation, cell communication, innate immune response, response to stress, response to wounding, cell adhesion, and regulation of proteolysis are more highly expressed during the WOI than during other phases of the menstrual cycle (reviewed in Gómez et al., 2015). These functional genomic studies have demonstrated that gene expression profiles differ depending on the phase of the cycle and hormonal treatment (Fig. 2).

The identification of sets of genes that reflect endometrial receptivity in natural cycles or in hormonal replacement cycles (HRT) lead to the development of a molecular diagnostic test, that is, Endometrial Receptivity Analysis (ERA) (Díaz-Gimeno et al., 2011). The ERA, first based on microarray data, is now performed using next generation sequencing (NGS) of 236 genes coupled to a computational predictor able to identify the optimal WOI of each patient (<https://www.igenomix.com/tests/endometrial-receptivity-test-era/>). The success of this test is based on its accuracy, which is superior to endometrial histology, and its reproducibility, as demonstrated in samples taken from the same patient up to 40 months apart (Díaz-Gimeno et al., 2013). This test is currently employed in clinical practice to identify the time frame in which each patient is receptive, thus allowing for personalized embryo transfer (pET) (Ruiz-Alonso et al., 2013).

Other studies have attempted to describe the transcriptomic profile of endometrial receptivity (Gómez et al., 2015). A recent meta-analysis found that 57 genes, including genes present in the ERA (i.e., SPP1, ANXA4, CLDN4, DPP4, GPX3, MAOA, and PAEP), were identified as potential receptivity biomarkers in multiple studies and are the most representative panel for predicting the WOI (Altmäe et al., 2017).

Cell-free RNA

Aspiration of the endometrial cavity was recently used for the analysis of potential markers of endometrial receptivity. The endometrial fluid (EF) is a complex biological fluid secreted by the endometrial glands. It provides nutrients for embryonic survival during the peri-implantation period and constitutes the microenvironment where the endometrial–blastocyst dialogue occurs before implantation. The molecular composition of EF has been investigated to identify markers of receptivity. A study analyzing the miRNA content of the EF throughout the menstrual cycle identified a set of 27 miRNAs differentially expressed during the WOI, with miR-30d being the most upregulated. This miRNA was shown to be internalized by trophoblast cells of the blastocyst, modulating blastocyst adhesion (Vilella et al., 2015). These results confirm the role of miRNAs in endometrial receptivity and their potential as biomarkers.

Clinical Assessment of Endometrial Receptivity

Recurrent Implantation Failure

A prospective clinical trial using ERA at the expected moment of receptivity found that 26% of patients with recurrent implantation failure (RIF) but only 12% of control patients (with one or no previous failed cycles) presented a displaced (advanced or delayed)

Fig. 2 Transcriptomic analysis of endometrial receptivity. Gene expression profiles of endometrial cycle can be used to analyze endometrial receptivity. Profiling the gene signature of endometrial receptivity: Clinical results. *Fertility and Sterility* **99** (4), 1078–1085, Copyright 2013, with permission from Elsevier.

WOI. Interestingly, when pET, guided by the ERA prediction of WOI, was performed on RIF patients, their clinical outcomes (implantation and pregnancy rates) increased to the levels observed in the control group, meaning that in those patients, the endometrial factor was responsible for the failed cycles. Thus, the diagnostic value of ERA was proven in clinical practice to improve pregnancy outcomes of women with RIF (Ruiz-Alonso et al., 2013).

Factors Influencing Endometrial Receptivity

Endometriosis

Endometriosis, a benign condition related to infertility, is characterized by the presence of endometrial cells outside the uterine cavity. Endometriosis does not affect embryo implantation in ovum recipients, meaning that the endometrial factor is not responsible for infertility in these patients. However, disruption of endometrial genes may be responsible for endometriosis (García-Velasco et al., 2015). To uncover the role of endometrial receptivity in endometriosis-associated infertility, ERA results of endometrial samples from infertile patients with different stages of endometriosis (stages I–IV) were compared to results of samples from patients without endometriosis. This pilot study showed that the transcriptomic profile of endometrial receptivity was similar in patients with or without endometriosis, regardless of the stage of the disease, indicating that endometriosis does not affect endometrial receptivity (García-Velasco et al., 2015).

Obesity

Obesity levels are increasing worldwide, and maternal obesity is linked to infertility. Obesity is associated with anovulatory problems, a lower implantation potential, increased miscarriage rates, and longer time-to-pregnancy in both spontaneous pregnancies and ART cycles. The poorer reproductive outcomes in obese patients may involve the egg, the embryo, the endometrium, or a combination. To clarify the role of endometrial receptivity in obesity-associated infertility, the ERA test was performed in infertile patients stratified by body mass index (BMI): normal-weight (BMI 18.5–24.9 kg m⁻²), overweight (BMI 25.0–29.9 kg m⁻²), and obesity class I (BMI 30.0–34.9 kg m⁻²), II (BMI 35.0–39.9 kg m⁻²), and III (BMI over 40.0 kg m⁻²). This study demonstrated that the transcriptomic profile of the endometrium during the WOI is altered in obese patients. The displacement of endometrial receptivity was more pronounced as BMI increased, in the proportion of non-receptive patients and in the levels of specific dysregulated genes (either up or downregulated). In conclusion, an altered endometrial receptivity may be a cause of infertility in obese patients (Comstock et al., 2017).

Ethnicity

Race or ethnicity may influence endometrial receptivity. The ERA test has been applied to patients of different ethnicities to elucidate whether differential genomic variants affecting ethnicity could influence the WOI. The transcriptomic profiles of endometrial biopsies of infertile women from the following ethnicities were compared: African ($n = 19$), Arabian ($n = 20$), Caucasian ($n = 1003$), East Asian ($n = 209$), Hispanian ($n = 45$), and South Asian ($n = 1244$). Most ethnic groups exhibited similar proportions of receptive and nonreceptive women; however, African women were distinct. In this group, there was a significant decrease in receptive patients with an apparent shift to a prereceptive phenotype. However in this study, the African women had significantly higher BMIs than the women from other groups, and this could bias the results obtained from the ERA test (see section **Obesity**). For this reason, further studies are required to clarify if ethnicity influences the acquisition and/or prediction of endometrial receptivity (Valbuena and Simon, unpublished data).

Endometrial thickness

A number of studies have investigated the association of endometrial thickness and receptivity, concluding that a thickness of 6 mm before progesterone administration in an HRT cycle indicates a receptive endometrium (see section **Ultrasound**). To corroborate these results using a reliable molecular method, ERA analysis was performed in retrospective endometrial samples classified by endometrial thickness at ultrasound into three groups: atrophic endometrium (Eth < 6 mm), normal endometrium (Eth 6–12 mm), and hypertrophic endometrium (Eth > 12 mm). A normal ratio of receptive and nonreceptive profiles were observed in samples from endometria with either normal or increased thicknesses. However, in samples from atrophic endometria, the percentage of nonreceptive profiles was significantly increased and accounted for more than 50% of the analyzed samples. Specifically, patients with atrophic endometrium presented a transcriptomic profile consistent with the prereceptive status, suggesting that the WOI in those patients is delayed due to insufficient growth of the endometrium (Valbuena and Simon, unpublished data).

Conclusions and Future Directions

Histological, biological, and physiological characteristics of the endometrium during the window of implantation are the result of transcriptomic and posttranscriptional changes. The ERA test is currently a clinically validated tool for diagnosing a displaced WOI and predicting the optimal time for pET, thus increasing the chances of successful implantation. However, the main limitation of the ERA test is that it requires an endometrial biopsy for analysis of the transcriptome. Future endometrial receptivity tests will ideally use minimally invasive techniques aimed at providing consistent results while avoiding pain and discomfort to the patients. The presence of RNA or single cells in the endometrial fluid will serve as the basis for developing noninvasive diagnostics and personalized ET without the need for a biopsy.

Technological advances in genetics may also lead to the development of less invasive diagnostic tools. Studies have already detected the association of single-nucleotide polymorphisms or genetic variants with several traits and diseases. Genome-wide association studies may help identify genetic variants in nonreceptive patients that are causative of a displacement of the WOI. This information could eventually be used to diagnose endometrial receptivity using blood samples. Furthermore, if such associations are identified, the relevant genes could be targets for novel lines of research the clinical management of infertile patients with endometrial factor.

Male Infertility

The definition of male infertility is the inability of a male to impregnate a fertile female. Infertility is a worldwide problem and according to Sharlip et al. affecting around 15% couples (Sharlip et al., 2002). Furthermore, nearly half of human infertility cases can be attributed to abnormal spermatogenesis (Kitamura et al., 2015). Genetic causes for male infertility are related to a limited number of cases in which altered seminal parameters (motility, morphology, and concentration) are directly associated with a genetic basis such as chromosome aberration or microdeletions at the Y chromosome (Jodar et al., 2017). The intricacies to define a genetic origin of this disease have led some researchers to suspect that both genetic and environmental factors contribute. The complex pathology, including the difficulty of isolating molecular abnormalities associated with this diagnosis makes it challenging to determine its underlying cause. However, recent research indicates the presence of epigenetic factors which may provide further insights into the pathogenesis of male infertility (Jenkins et al., 2017). The increased usage of human assisted reproductive technologies (ART) has created an enormous interest in identifying, diagnosing and potentially treating male infertility. In recent years the advancements in the field of ART have provided indirect evidence for the role of epigenetic mechanisms in male infertility (Kitamura et al., 2015).

Epigenetics

Epigenetics refers to changes in the phenotype caused by mechanisms other than changes in DNA sequences. Nearly all the cells in multicellular organisms share an identical genotype however, the diversity in cellular function is based on gene expression profiles that differ among individual cell types. Mechanisms such as DNA methylation, non-coding RNAs, chromatin remodeling and histone modification chemically and structurally alter the expression of genomic region (Tvrda et al., 2015). These various epigenetic signatures are specific to each individual cell type and make up the cell epigenome. The epigenome is thought to reflect the organism developmental history and past environmental influences. The dynamic and tissue specific nature of the epigenome allow for flexibility in gene expression which can lead to changes in phenotypes in the organism. Throughout the process of mitosis, majority of the epigenetic landscape is replicated from one cell to another. During reproduction, some but not all of the epigenome is reset in the embryo (Murphy et al., 2014). The remaining epigenetic signatures after the erasure event may allow the transfer of phenotypic traits on the subsequent generations (Tollefsbol, 2014). Thus, the epigenetic modifications of the germline (sperm and egg) can have long-term consequences as the altered epigenome can be transmitted to the embryo and this process is referred as transgenerational epigenetics (Guerrero-bosagna and Skinner, 2014).

Epigenetic transgenerational inheritance is a new and rising subfield which studies the impact of non-genetic inheritance on epigenomes, specifically, transcriptomes of all subsequently derived somatic cells in the embryo. The transcriptome consists of the small fraction of the genome corresponding to genes and protein coding regions of the genome that have an influential role in the development of the embryo (Guerrero-bosagna and Skinner, 2014). This field of study provides a mechanism through which exposures in previous generations influence the phenotypes of subsequent generations through epigenetic regulation. Germ cells are vehicles of inheritance that transmit genetic information from one generation to the next. Male and female mammalian germ cells inherently differ in their development, morphology and means of fertilization. Thus, it is not surprising that divergent epigenetic mechanisms accompany these cell types (Murphy et al., 2014).

DNA accessibility differs throughout an organism lifespan resulting in distinct sets of active genes varying at each developmental stage. Sperm cells are highly specialized. Their production occurs during spermatogenesis, a process involving extensive cellular, epigenetic and chromatin changes (Oliva and Castillo, 2011). Life cycle of the sperm begins at the embryonic stage as a specialized pool of somatic cells called primordial germ cells (PGC). PGC undergo an erasure of DNA methylation and histone replacement event, essential for proper sperm and offspring development (Murphy et al., 2014). The replacement of the majority of histones with protamines helps promote nuclear compaction, increases sperm motility and insulates the genome against harmful molecules in the female reproductive tract (Jenkins et al., 2017). After gonadal maturity, spermatogenesis ensues. Spermatogenesis takes place in the seminiferous tubules of the testes in three distinct phases: (i) an undifferentiated diploid male germ cell differentiates into two different types of spermatogonia. Spermatogonia type A replicates through mitosis and maintains the spermatogonia population in the testes. Spermatogonia type B can enter into meiosis and further differentiate into spermatozoa. (ii) Spermatogonia type B increase in size turning into primary spermatocytes. Further mitotic divisions convert the diploid spermatocytes into haploid spermatids. (iii) The round spermatids continue to undergo nuclear and morphological changes to become mature spermatozoa. Spermatozoa continues to mature as it transits along the epididymis in order to acquire both motility and fertilization potential to reach full maturation (Fig. 1) (Jodar et al., 2017). After the completion of sperm maturation, they are then able to swim and fertilize an oocyte. During the complex process of fertilization, sperm travels through the female reproductive tract, penetrates the cumulus oophorus, binds and enters the zona pellucida and then the oocyte. At this stage, there is a second epigenetic reprogramming event which involves DNA methylation erasure and histone reassembly following paternal DNA. The molecular reasons underlying the reassembly remain unknown. After this stage, the zygote initiates development and continues to totipotent conversion (Murphy et al., 2014).

DNA Methylation

One of the most studied epigenetic marks is DNA methylation. This methylation occurs on the cytosine residues in the cytosine phosphate guanine (CpG) dinucleotides. Methylation near promoter regions prevent the expression of that gene (Güneş and Kulaç, 2013). The process of initiation and the maintenance of these methylation marks is controlled by a family of proteins, the DNMT (DNA MethylTransferases) (Portela and Esteller, 2010).

Throughout the male germ cell development, there are two instances during which epigenetic reprogramming takes place: during primordial germ cell development and post fertilization in the zygote. The first epigenetic reprogramming event is initiated when the PGCs begin to proliferate and migrate to the genital ridges where the future gonads will reside. During the primordial germ cell

Fig. 1 The germ cells population lies on the basal lamina of the convoluted seminiferous tubules. Type A spermatogonia undergo mitosis: one of the daughter cells renew the stock of type A spermatogonia, the other becomes a type B spermatogonia. These divide and their daughter cells migrate towards the lumen. They differentiate themselves thereby into sperm cells up to the outer surface of the epithelium where the separation of the cytoplasm is not complete. Modified by Stephanie E. King from *The Reproductive System in Human Anatomy & Physiology*, 9th edn. Benjamin Cummings—An imprint of Addison Wesley Longman, Inc. 2012.

reprogramming event, the erasure of epigenetic marks differentiates somatic cell lineages and inserts new marks to promote sex specific imprinting patterns and germ cell function. The demethylation event occurs asynchronously across the genome suggesting the presence of regulatory mechanism to control the pace and location of DNA demethylation (Murphy et al., 2014). Although a large portion of the genome undergoes a rapid demethylation event, some portion of the genome retains methylation. The majority of the resistant loci consists of long terminal repeat transposable elements along with long and short interspersed elements. It is predicted that the methylation prevents the activation from these retroviral elements thus protecting the germline from their activation (Murphy et al., 2014).

The second reprogramming event occurs after fertilization when paternal DNA is demethylated and the methylation patterns are reset in the developing embryo (Fig. 2). After fertilization, DNA is demethylated and methylated in the developing embryo resulting in a reset of parental germlines. During this process, epigenetic marks specific to germ cells are reset for early embryonic pluripotency. This active removal of methylation is coordinated by Ten-eleven translocation enzymes (TET). The demethylation event of the zygote takes place prior to the first cell division and is thought to occur through active hydroxy-mediated demethylation. This reset is not complete thus some methylation marks are maintained in the developing embryo (Fig. 2). Recently, researchers have used genome wide association studies (GWAS) to identify specific loci that escape the reprogramming event. The maintenance of certain methylation patterns in the embryo are known as imprinted genes. These loci have become the foundation for identifying pathways that are biochemically regulated by epigenetics (Murphy et al., 2014). These GWAS have also indicated that epigenetic marks on the sperm not only facilitate its own development but also the development of the embryo (Murphy et al., 2014). In the developing embryo, regulatory processes such as genomic imprinting and X chromosome inactivation are continued to be influenced by gene processes including DNA methylation (Jenkins et al., 2017). Methylation events continue to occur throughout development in a tissue specific manner.

Chromatin Remodeling

The process of fertilization and movement of sperm along the female reproductive tract requires the coordination of many physiological events. Modifications of the sperm structure is essential as it progresses through potentially harmful environment in the female reproductive tract. Regulatory mechanisms following sperm maturation replaces 90%–95% of histones with protamines (Fig. 3) (Kim, 2014). The replacement of histones with small, arginine rich molecules known as protamine allows for compaction of the nucleus. The condensation of the sperm nucleus, with its decreased surface area, increases sperm motility and protects the sperm genome from oxidation and other chemicals in the female reproductive tract. The compact packaging of the genome prevents the binding of transaction factors prematurely. Immediately following fertilization, protamines are translocated with histones (Güneş and Kulaç, 2013).

Histone Modification

Histones—basic proteins rich in lysine and arginine—induce packaging of the DNA into structural units called nucleosomes. H2A, H2B, H3, and H4 histones are found in the nuclei of the nucleosomes (Fig. 3). These units are formed by combination of

Fig. 2 DNA methylation levels throughout life. Modified from Jirtle, R.L. and Skinner, M.K. (2007). Environmental epigenomics and disease susceptibility. *Nature Reviews. Genetics* 8(4), 253–262.

Fig. 3 Structure of DNA, chromatin, and histone. Chromatin is an instructive DNA scaffold that can respond to external cues to regulate the many uses of DNA. A principle component of chromatin that plays a key role in this regulation is the modification of histones. Histones are proteins found in eukaryotic cell nuclei. They package and order DNA into structural units called nucleosomes. Modified from Kim, Y.Z. (2014). Altered histone modifications in gliomas. *Brain Tumor Research and Treatment* 2, 7–21, and the cellular level of organization in *Principles of Anatomy and Physiology* 11th edn. by G. J. Tortora and B. H. Derrickson, John Wiley and Sons.

two H3–H4 dimers and two H2A–H2B dimers bound by H1 histone proteins (Campos and Reinberg, 2009). Histones can change the DNA-binding capacities and interaction of other regulatory factors with DNA. Histone modifications include acetylation, methylation, phosphorylation, and ubiquitination. During sperm formation, in the haploid phase of spermatogenesis where round spermatids mature into spermatozoa, histone variants are incorporated to restructure chromatin. In human, mouse and fly, testes-specific variants of H1, H2A, H2B, and H3 displace canonical histones prior to incorporation of transition proteins and protamines (Godde and Ura, 2009; Govin et al., 2004; Montellier et al., 2013). Some in vitro studies have demonstrated that some of these variants cause nucleosome destabilization (Güneş and Kulaç, 2013). Other histone variants mark specific chromatin domains. For example, in mouse spermatids, H2AL1/2 are incorporated into heterochromatic pericentric chromatin (Samson et al., 2014).

Acetylation of histone H3 and H4 usually leads to open chromatin configuration and active transcription by facilitating the binding of transcription factors. Deacetylation and methylation are generally correlated, they are associated with an inactivation of the transcription. A methylation of lysines localized on the histone tails is another regulatory mechanism. H3K9 and H3K27

histones are usually methylated and thus linked with inactivation. However, methylation of histones takes place both in active and inactive chromatin sites. When H3 and H4 histone protein tails undergo modifications, it sometimes regulates transitions between active and inactive chromatin states through a reverse mechanism called histone code.

Histone modification and changes in its composition play important roles in chromatin modifications. These modifications are required for normal meiotic process and later maturation of gametes. Following termination of meiotic divisions, the sperm cells undergo developmental changes. In fact, some histones on the X chromosome label and retain some methylated histones H3K9me2. A global remodeling in haploid spermatids occur at a lower rate. In mature sperm, H2B was found to be the most frequently expressed histone. H3K4me3 is usually found on genes regions involved in spermatogenesis while H3K4me2 in regions rich in developmental genes. Furthermore, the hypermethylation of histone H4 is responsible for the replacement of histones by protamines in haploid spermatids (Güneş and Kulaç, 2013).

Thus, the histone packaging process is an evolutionary and developmental procedure for spermatogenesis. DNA methylation and histone modification both play an important role in the regulation and control of gene expression.

Sperm Non-Coding RNA

The original observations suggest that DNA methylation alterations and histone modifications in the sperm were crucial; noncoding RNAs have, subsequently, also been shown to be involved (Skinner, 2014). Sperm is known to contain a diverse population of RNAs including non-coding RNAs which can be long or small (Skinner, 2015). Abundant small non-coding RNAs retained in spermatozoa include miRNAs and piRNAs. Some of them are essential to the early embryo development like miR-34c which is required for the first cellular division. Other non-coding RNAs include transposable elements, annotated lnc-RNAs, intronic retained elements, exonic elements, chromatin-associated RNAs, small-nuclear ILF3/NF30 associated RNAs, quiescent RNAs, mse-tRNAs, and YRNAs (Jodar et al., 2013). Some non-coding RNAs are known to act as epigenetic modifiers, such as histone modifications and DNA methylation, thus playing a role in transgenerational epigenetic inheritance.

This new area of study holds great promise for the development of this field. For example, comparing the differential ncRNAs profiles of infertile versus fertile individuals should help understand the regulatory pathways contributing to male infertility.

Clinical Issues

Aberrant epigenetic changes in male germ cells can lead to clinical issues. Abnormal methylation patterns and aberrant protamine insertions have been known to influence male fertility. CpG islands at gene promoter regions which are usually hypomethylated are especially susceptible to aberrant methylation for specific genes such as DAZL and MTHFR or imprinted loci. Epigenetic abnormalities in these regions are strongly associated with various forms of infertility and sperm defects in men (Carrell, 2012). Proper DNA methylation is especially important in imprinted genes as these genes are inherited directly from the parental germline and may have a transgenerational effect. Men with low sperm counts; oligospermic patients, (less than 10 million spermatozoa per 1 mL of semen) have been shown to contain a greater number of DNA methylation errors compared to men containing normal sperm counts. Furthermore, these imprinted loci are suspected to be inherited by the offspring during in vitro fertilization (IVF) treatments. Disorders due to defective imprinted gene expression can cause severe developmental defects including Angelman and Prader-Willi syndromes. Furthermore, children born from IVF treatments are found to have slightly greater incidents of imprinting disorders than children who were naturally conceived. This raises questions regarding the status of sperm methylome used in IVF treatments.

The use of assisted reproductive technologies have increased in recent years. Understanding the epigenetic processes underlying male factor infertility will aid proper diagnosis as well as, help develop sperm selection techniques used for IVF (Murphy et al., 2014).

Epigenetic dysfunction can also occur in spermatogenesis and may be a contributing factor in male infertility. The proper replacement of histones with protamines is a crucial step in male gametogenesis as reduced protamine levels are associated with oligospermic men. The differential DNA methylation patterns observed with male infertility is accompanied by altered protamine ratio and indicate the interaction between epigenetic phenotypes. Like the protamine, histones also carry programmatic information and thus can possibly contribute to male infertility. Histone retention has been found to occur sporadically throughout the genome, and loss of histone retention at imprinted loci is often associated with male infertility.

Epigenetic modifications are well studied in both DNA methylation and histone retention. Yet, the topic of chromatin remodeling and of non-coding RNAs have been understudied. More comprehensive understanding of epigenetic influences on male factor infertility can help further sperm selection techniques for artificial reproductive technologies.

Introduction to the Relationship Between Genetics, Epigenetics, and Gene Regulation

In individual multicellular organisms each cell is generally made up of identical DNA (aside from germ cells which only contain a haploid genome). Despite this, each unique cell type within that individual is able to arise using the same genetic blueprint as all other cell types and to facilitate normal functionality. In humans, there are more than 200 different, and highly unique, cell types in every individual that arise from the same genetic blueprint. Thus, a fundamental question in all of basic cell biology and genetics is simply, "How can so many diverse cell types arise from the same DNA code?" While the answer to this question is incredibly complex and in some cases yet to be fully elucidated, in short, the answer has to do entirely with gene regulation, not the genetic code itself. With the rate of advancement and focus on genetics following the sequencing of the human genome, it is important to note that genetics, while incredibly important, makes up only a portion of the story of human physiological function. Another key component to human physiological function is gene regulation, of which a key component is the epigenetic landscape.

The classic definition of an epigenetic mark is a molecule or modification, which can alter gene expression, is modifiable during the life of an individual, and is heritable. Under this definition, two major components of the epigenome exist, DNA methylation and histone modifications. Each of these marks can have profound impacts on gene regulation. DNA methylation typically occurs on the 5' carbon of cytosine nucleotides in the DNA, most frequently in the context of cytosine-phosphate-guanine (CpGs) dinucleotides. These CpGs are commonly enriched at the promoter region of genes and when the CpGs are methylated, they tend to inhibit transcription by blocking the binding of transcriptional machinery (Jaenisch and Jahner, 1984). There is a great deal of evidence that DNA methylation is influential in gene regulation in many other contexts beyond promoter methylation as well. Histone modifications also play a key role in gene regulation. In brief, histone tail modifications of different types help to drive gene inactivation or transcription. These modifications come in many flavors including ubiquitination, acetylation, methylation, etc. These types of modifications on both histones and CpGs play a key role in gene regulation (with both silencing and activation) and help to drive the differentiation of the various cell types in humans (Fig. 1).

Recently, a much more loose definition of epigenetics has been used to categorize other key contributors to gene regulation that are also highly modifiable in an individual over time but that are not directly heritable (at least in the same way DNA methylation and histone modifications may be). These marks include the many different species of RNA molecules. The main form of RNA that is assessed in this context are small, non-coding RNAs (ncRNA). There are many different forms of these RNAs including micro-RNAs, piRNAs, siRNAs, etc. There is even evidence that tRNA fragments may play a role in some epigenetic regulation. Though many of these marks do not fit into the conventional definition of epigenetic marks, for many reasons their roles and potential impact are so similar many researchers cluster these marks with the more commonly considered epigenetic signatures.

Fig. 1 Illustration depicts common epigenetic marks and associated gene activation or repression. The presence or absence of DNA methylation at gene promoters can regulate the activation or silencing of gene transcription. Similarly, histone modifications including ubiquitination (ub), monomethylation (me), dimethylation (me2), trimethylation (me3), and acetylation (ac) at various histone (H3, H2A, H4, H2B, etc.) can drive gene regulation. These histone modifications typically occur at histone tails on lysine residues (K4, K9, K27, etc.).

Sperm Epigenome

The mammalian sperm epigenome is among the most unique and specialized epigenetic landscapes known in biology. The sperm's unique epigenetic signatures are required to facilitate the normal function of this incredibly unique cell type. The human sperm epigenome specifically has been the focus of a great deal of study in recent years to better understand the nature of this unique epigenetic landscape and the impact of alterations to DNA methylation and histone modifications found therein. These studies have revealed a dynamic series of reprogramming events during spermatogenesis that make the sperm capable of its specialized function, namely the safe delivery of the paternal DNA blueprint through the female reproductive tract to fertilize the ovulated oocyte. To facilitate this functionality, the sperm nucleus becomes remarkably, highly condensed to 6–20 times more dense than somatic cell nucleosome-bound chromatin (Ward and Coffey, 1991). This compaction occurs as a result of the stepwise replacement of histone proteins with protamine proteins. The protamination process occurs throughout spermiogenesis, where histones (both canonical and testis specific variants) are replaced by transition proteins. These same transition proteins are then replaced by protamine proteins, which then form tight toroid structures to highly condense the sperm nucleus, facilitating motility and effective DNA protection from free radicals and other potential DNA damaging agents that the sperm are likely to encounter. Such tight packaging also generates a transcriptionally quiescent cell.

In addition to the massive chromatin reorganization that occurs throughout spermatogenesis, there are also quite unique DNA methylation signatures found in the mature sperm. It appears that these signatures are established early in spermatogenesis (perhaps as early as the adult germ line stem cell in humans) and are held relatively stable throughout sperm maturation. Many interesting DNA methylation profiles can be found in the mature sperm, but among the most interesting is the global hypermethylated state of the sperm DNA (most likely driven by methylation at repeat elements and other sites in the genome). This is believed to contribute to some degree to the quiescent state of mature sperm, though not all of the sperm genome is hypermethylated. In fact, there are often low methylation levels at gene promoters. Even more interesting is the enrichment of DNA demethylation intermediates, most notably 5-hydroxymethylcytosine (5-hmC), at the promoters of genes important in development. This enrichment is coupled with “bivalent” histone modifications at the same locations. These “bivalent” domains are defined by histone modifications that both promote and repress gene activation. It is believed that these domains, where both bivalent histone modifications and 5-hmC are enriched, are poised for gene activation. It is no surprise then to note that such domains are most commonly seen in embryonic stem cells. It is for this reason that many believe that the sperm epigenome is a direct and key contributor to establishing early embryonic development.

One of the most interesting facets of the sperm epigenome relates directly to the unique nature of the cell. In effect, sperm must acquire all of the epigenetic marks that are essential for its main function to deliver the DNA blueprint to the egg. However, the cell must also remain competent to drive and/or contribute to processes in the embryo. Because of the massive and dynamic reprogramming that occurs in the sperm and immediately following fertilization, the two roles of the sperm appear to be at odds with one another. Specifically, it is known that histone modifications are important regulators of gene activity but in sperm we also know that, through the process of protamination, the majority of the histones, and their associated modifications, are removed and replaced by protamine proteins. Further, immediately following fertilization there is a massive erasure of DNA methylation signatures. Taken in this context, there has historically been little interest in the contribution of the paternal epigenome to the embryo and beyond. Remarkably, recent evidence has shown that protamination and active zygotic demethylation are incomplete leaving some fraction of histones and DNA methylation marks in place. In fact, evidence suggests that not only do some histones escape protamination, but that the histones that are retained are enriched at gene promoters important in embryonic development (Hammoud et al., 2009). Thus, the previously held view that the sperm epigenome is of little significance has been largely dismissed.

As a result of the many roles of the epigenetic signatures in sperm, investigating these marks actually offers tremendous insight into both the history of the cell itself (spermatogenesis, etc.), as well as the potential for the generation of a successful pregnancy. Thus, the paternal epigenome offers unique opportunities for study (Fig. 2). In fact, sperm DNA methylation in particular offers the unique opportunity to observe the relative epigenetic environment in the adult germ line stem cell. This is due to the fact that the DNA methylation profile in sperm changes very little throughout the process of spermatogenesis. In fact, it appears that in mammals virtually no change occurs from the adult germ line stem cell all the way through to the mature sperm. Researchers are thus able to examine the nature of the epigenome and potentially be able to better diagnose the etiology of alterations seen in the mature sperm. Further, because the sperm epigenome appears to play a key role in the embryo, there is very real potential to identify signatures that

Fig. 2 Epigenetic signatures in the sperm are both reflective of the spermatogenesis process as well as potentially predictive of reproductive outcomes.

may be predictive of fertility in general, fertilization, embryo quality, and even offspring health. These potentials are what drive the great deal of recent interest in the sperm epigenome.

Sperm Epigenetics and Sperm Abnormalities

Many studies have been performed in an effort to understand the link between the sperm epigenome and various forms of male infertility phenotypes. Recent studies have observed alterations to global sperm DNA methylation profiles that appear to be associated with many forms of infertility including low sperm count and motility (Montjean et al., 2015). Interestingly, similar findings were seen when assessing far more high-resolution data of sperm abnormalities and DNA methylation signatures. Specifically, it was found using microarray technology that DNA methylation signatures were significantly altered in the sperm of patients who suffered from either low sperm viability or low motility (Jenkins et al., 2016a). Importantly, these epigenetic alterations were found at loci (particularly in the low viability cohort) that are important in meiosis and/or spermatogenesis (Jenkins et al., 2016a). A great deal of research has also suggested that DNA methylation at imprinted regions such as MEST, H19, and IGF2 are commonly altered in infertile men (Boissonnas et al., 2010; Poplinski et al., 2010). Such findings strongly supports the assertion the sperm methylome provides an excellent opportunity to observe changes that may have occurred early in spermatogenesis, which ultimately affect sperm physiological function.

Further studies have also shown alterations to histone modifications associated with various forms of infertility. In one study, it was shown that there were both alterations in histone modifications as well as in the regions in which histones were retained (through the process of protamination) in patients who had various forms of male infertility (Hammoud et al., 2011). Interestingly, in men who were infertile due to abnormal protamination it was found that methylation patterns were disrupted as well at the CREM promoter (Nanassy and Carrell, 2011). In a recent study of smokers it was shown that smoking affected histone retention, and that these individuals also displayed adverse fertility impacts (Hamad et al., 2014). Clearly, a great deal of data suggest that assessing the sperm epigenome may be informative in determining the etiology of the processes involved in the many forms sperm abnormalities.

Sperm Epigenetics and Fertility

While it is clear that altered sperm epigenetic patterns can affect normal sperm function, including everything from sperm viability, morphology, motility, and even general production (resulting in low sperm counts), the impact of the sperm epigenome on male fertility is less directly clear. However, we do have some recent evidence, suggesting that the impact of the sperm epigenome on fertilization and general male fertility is not only possible but quite probable. In a recent study of individuals attempting to conceive who had not been screened for any form of infertility, some interesting patterns were found that were associated with fecundity and sperm DNA methylation signatures. Specifically, the study compared individuals who were able to conceive within 2 months of attempting conception to individuals who were unable to achieve a pregnancy within 12 months of attempting to conceive. It was found that a small number of DNA methylation alterations occurred readily in the group that never conceived compared to the group that did conceive in the first 2 months of attempting conception (Jenkins et al., 2016b). Of particular interest was the location of these alterations. It was found that only two sites had altered methylation signatures, specifically HSPA1L and HSPA1B. These two tightly related genes are found in the same genomic neighborhood and also share similar functionality. The relationship of these functions to infertility specifically is not well understood, however the fact that across the entire genome these are the two most significantly altered genes that were identified is intriguing. Clearly, in addition to being associated with various forms of sperm abnormalities, the sperm epigenome is also associated with fertility and fecundity in general.

Sperm Epigenetics and Embryogenesis

As described above, the sperm epigenome appears to be not only reflect the process of spermatogenesis but is also poised to facilitate normal early embryogenesis. This hypothesis is based on data that suggests that both sperm DNA methylation signatures and histone modifications (or nuclear protein composition in general) appear to be poised to affect gene activation at genes essential for developmental processes in the embryo. Adding credence to this idea is the fact that in many important ways the epigenetic signatures in sperm reflect that of an early embryonic stem cell. With this in mind, it is not surprising then that alterations to the sperm epigenome may result in abnormal embryo development, which is particularly important in cases where this is followed closely such as in in vitro fertilization (IVF). In some animal models the association between the sperm epigenome and embryogenesis has been tested quite directly. In a number of early studies of sperm DNA methylation it was found that chemical alteration of the methylome (with the use of 5-azacytidine) resulted in decreased general fertility in mice, but also resulted in increases in embryo mortality (Seifertova et al., 1976). Further studies have shown, on the global scale that a similar treatment in both mouse and rat resulted in increased pre-implantation loss (Doerksen and Trasler, 1996; Kelly et al., 2003; Oakes et al., 2007). Clearly, the epigenetic profile in sperm are important for the early embryo.

In more direct tests of the impacts of alterations in sperm epigenetic profiles in humans, similar results were identified to those shown in other mammals. In a recent study, human sperm DNA methylation profiles were compared between men who sired embryos of varying degrees of quality through IVF (Aston et al., 2015). These individual samples were categorized based on both the quality of their embryos and also compared a fertile cohort. These results indicated that the DNA methylation signatures in sperm were quite predictive of an individual's fertility status and that there was also evidence to suggest that the sperm methylome could predict the likelihood of generating high quality embryos (good morphology and implantation potential) through IVF. While a great deal more work is required in this regard, it is intriguing that such patterns exist and that they may offer some degree of diagnostic utility. While not fully elucidated, from the available evidence it is clear that the sperm epigenome is not only impactful in respect to sperm function but that it is also important in normal embryonic development.

Sperm Epigenetics and Impact on the Offspring

The sperm epigenome is important in normal sperm function and even in early embryonic development, but there is also intriguing evidence to suggest that paternal epigenetic patterns have the capacity to affect offspring health. Specifically, epidemiological evidence has shown that offspring sired by older fathers have an increased incidence of neuropsychiatric disorders (including autism, schizophrenia, and bipolar disorder), some forms of cancer, and trinucleotide repeat disorders (Hare and Moran, 1979; Miller et al., 2011; Frans et al., 2013; Brunner et al., 1993; Oksuzyan et al., 2012; Yip et al., 2006). These data are quite striking and have brought to light the potential role that epigenetics may play in the process.

Two recent studies have examined this question directly in both human and mouse. In the mouse model it was shown that there are very distinct DNA methylation alterations that occur in the sperm methylome that occur with age and that there were associated alterations to offspring behavior that mimicked that of neuropsychiatric disease (Milekic et al., 2015). A year prior to this publication was a study in humans that showed strikingly consistent alterations to the sperm methylome at distinct regions throughout the genome. Of most interest in this specific study were the regions at which the sperm DNA methylation alterations occurred most frequently. It was found that the regions that were epigenetically impacted in the sperm genome were enriched at genes known to be associated with bipolar disorder and schizophrenia (Jenkins et al., 2014). Such findings were remarkable on their own, but taken into the context of chromosomal position these findings become even more intriguing. In the human study there appeared to be some enrichment of age-affected sites in sub-telomeric regions. Remarkably, it has been shown in mouse models that these same sub-telomeric regions are some of the few that escape the wave of methylation erasure and reprogramming that occurs in the zygote and primordial germ cells (Guibert et al., 2012). Taken together, there is real potential for the alterations identified in the sperm epigenome to actually impact the offspring, in this case, in a negative way.

Aging-associated epigenetic alterations to sperm DNA demonstrate one way in which the sperm epigenome can affect even the offspring. This represents only one of many sources of evidence which all point to the same conclusion that the sperm epigenome can impact the offspring and even future generations. In one recent study, it was shown that DNA methylation alterations at the POMC promoter in sperm induced by alcohol exposure in utero were transmitted over multiple generations through the paternal germ line (Govorko et al., 2012). Other studies have shown clear effects on the offspring as a result of other exposures in the father, which did not result in genetic mutations, but instead were the result of epigenetic alterations. One such study examined exposure to nicotine in male mice that sired offspring. The nicotine exposure in these males induced a protective phenotype (enhanced metabolic tolerance of the nicotine) in the offspring (Vallaster et al., 2017). Clearly, while many questions still remain, there is a great deal of evidence that establishes an important contribution to offspring phenotype and health from the father. It also appears quite likely that the mechanism driving this effect is at least in part the sperm epigenome.

Future Directions

Because of the far-reaching implications of epigenetic alterations in the sperm, from male fertility, embryo health, and even offspring phenotypic modifications, it is important that we focus a great deal of research effort to fully elucidating the mechanisms that underlie these processes. Because of the extremely unique nature of the marks (particularly in sperm) and tissue availability, there is a tremendous amount of potential for diagnostic tests, which screen epigenetic signatures. Some work has already been performed with good success. The nature of methylation data is that it provides a tremendous amount of information about the state of a given tissue type (normal or abnormal) and thus this data type lends itself very well to newly available machine learning approaches for predictive model generation. Such models have the potential to improve diagnostic testing in a field, male infertility, where such effective diagnostic testing is lacking.

While much work is still required, the available data clearly demonstrate that alterations to sperm epigenetic patterns are associated with various forms of abnormal sperm phenotypes, male infertility in general, abnormal embryogenesis, and even offspring health. Future work must rely on human research as well as animal models to fully elucidate the mechanisms that underlie the relationships between epigenetics and phenotypes. Further, because of the amount of data that can be generated in epigenetic analysis, predictive model generation will be a key component to future analyses.

Cryopreservation of Sperm

Sherman Silber, Infertility Center of St. Louis, St Luke's Hospital, Chesterfield, MO, United States

Introduction

The basic principles for cryopreservation of sperm are not different from cryopreservation of embryos, eggs, and ovarian tissue. However freezing with sperm is much easier because there is such a minute amount of water in this small, otherwise highly specialized gamete. In fact very little advance has been made in sperm freezing research, because the results seem to be so adequate with the simplest of methods (Keel and Webster, 1990; Mortimer, 1994; Morshedi, 1990; Oshima and Burger, 1993; Hallak et al., 2000; Bhattacharya et al., 2006; Hammadeh et al., 2001; Nallella et al., 2004; Freezing Medium - TYB with Glycerol and Gentamicin, 2016; Sadri-Ardekani and Atala, 2014; Sadri-Ardekani et al., 2009, 2011, 2013, 2014; Polge, 1957; Bunge and Sherman, 1953; Brinster, 2007; Brinster and Zimmermann, 1994; Bahadur et al., 2000; Brinster and Avarbock, 1994; Keros et al., 2007; Hovatta, 2001).

For embryo or egg freezing, much more precise methodology is required because 70% of these cells is water. When the intracellular water freezes, it crystalizes, and occupies a larger volume and is less dense. That is why ice cubes float. But it is also why cells are killed by freezing.

So all methods of cryopreservation rely on preventing intra cellular ice crystal formation. However I will describe, in addition to routine sperm cryopreservation, a simple new method for freezing individual sperm for difficult cases of TESE. Slow cooling results in preferential freezing of water on the outside of the cell, where the osmolality is lower. That raises the osmolality extracellularly. This in turn draws water out of the sperm making the inside even more hyperosmolar. Thus as the temperature cools gradually and ice forms preferentially on outside of the cell, that pulls water out of the cell, and then cryoprotectants enter the cell and lower the freezing point inside the sperm cell even further. Eventually the inside of the sperm actually vitrifies when the temperature is low enough and the osmolality is high enough in this extremely low volume cell.

This slow cooling rate for sperm here need not be so precise as it is with using a controlled rate freezing machine (like for slow freeze of embryos). In fact one can simply have a vial containing sperm mixed with cryoprotectants over an open liquid nitrogen dewar, vapor freeze it and then plunge it into the tank. Before holding over liquid nitrogen vapor, it can be first put in an ordinary refrigerator at 4°C. It is amazingly simple. It is the same principle as slow freezing of embryos but it does not have to be very precise, because the water content of sperm is so low. Despite the crudeness and lack of graduality of such sperm freezing and thawing protocols, the effectiveness of this vapor slow freeze approach for sperm cryopreservation is very reliable.

Methodology Details

For sperm freezing and simple testicular tissue freezing in sophisticated studies documented by Brinster, Sadri-Ardekani, Shinohara, and Van Pelt with sperm and spermatogonial stem cells (SSC'S), the best results were remarkably obtained with just this simple vapor freeze. A media containing test yolk buffer (Irvine Scientific (YP)), with glycerol and gentamycin is the usual favorite. It contains 20% egg yolk USDA certified, and 12% glycerol. The steps are as follows:

1. The sperm simply liquefies at room temperature.
2. Use a thawed 5 ml vial of medium.
3. Add liquefied sperm sample drop by drop very slowly over 30 seconds until there is a 50:50 ratio of semen or sperm to media, and mix slowly but very thoroughly. A failure to do this mixing slowly, and drop by drop, will result in complete failure.
4. For this manually assisted vapor freeze method we recommend the mixture should be placed in the refrigerator (2–5°C) for an hour before putting over the liquid nitrogen vapor.
5. Then after an hour plunge the vial into liquid nitrogen at –196°C for storage.

We have sent difficult samples to complex research programs all over the world with this simple approach of sperm freezing, and indeed testicular tissue freezing, and remarkably, this works well with no apparent need for any further improvement. So this simple sperm freeze protocol using glycerol and egg yolk, with vapor phase freeze followed by plunging, is quite adequate for sperm, and for testis tissue. We are benefited by the tiny water content of sperm and by the very small size of the sperm cell. Glycerol is a reasonable cryoprotectant for sperm, but the TEST yolk gives better results by stabilizing the membrane. These are not effective cryoprotectants for eggs or embryos.

Media for Sperm Freeze

Freezing medium TYB contains TEST-yolk buffer (TYB) to recover more motile sperm postthaw than glycerol-only media (Hallak et al., 2000; Nallella et al., 2004). TEST-yolk buffer is a semen extender and cryobuffer that can be paired with glycerol to achieve high sperm motility and viability. The egg yolk is from USDA certified virus-free flocks and washed from the sperm after cryopreservation. Freezing medium TYB is also the only CE-marked and FDA-approved sperm freezing media containing TYB and glycerol. As one of the most referenced sperm cryopreservation media worldwide, freezing medium TYB has become the routine. The media contains:

- 20% egg yolk from USDA certified SPF (virus free) laying flocks, heat inactivated at 56°C for 30 min
- 12% glycerol
- 10 µg/mL gentamicin sulfate

The most important use of sperm cryopreservation is for donor sperm banks, or for cases where the man wants to preserve his sperm before undergoing cancer treatment, or vasectomy. These would be all cases of men with normal spermatogenesis. However, when there is severe oligospermia in an infertile male, who would require IVF and ICSI with every few sperm, a more precise method is required, and here again it can be simple.

For freezing single sperm, or just a few or small number of sperm (e.g., derived from TESE with nonobstructive azoospermia), one can purchase a small platform with tiny microwells, and put just 1 µL of sperm freezing solution in each tiny well. Slip that into the ICSI dish and pick the individual sperm from the microdroplet of the ICSI dish, and drop them into the 1 µL droplet of cryoprotectants solution. Then plunge that small platform into liquid nitrogen directly, after holding in vapor.

Frozen Donor Sperm: Clinical Application

In the past, if the husband had no sperm in his ejaculate, the only solution was for the wife to have artificial insemination with donor sperm. Since we have developed the ICSI technique, there are now very few couples who would need to consider donor sperm, because the vast majority of previously hopeless cases of male infertility can now be treated successfully with ICSI. In most cases in which ICSI is not successful for dealing with male infertility, it is because of the wife's eggs, not the sperm. However, there are still a small number of cases in which no sperm at all can be found with TESE-ICSI, or in which the sperm are completely abnormal. Therefore, the need for donor sperm banks may have dwindled, but some couples will still have this need. The process of using donor sperm for couples for whom there is no alternative is as follows.

For counseling, in a sense, using donor sperm is really no different from adoption. It is simply a matter of adopting sperm. You're adopting the baby at a much earlier stage prior to conception. Using the sperm of a well-selected anonymous donor is the most realistic and sensible solution for the few couples who simply have no sperm at all, even in the testes. The use of donor sperm or donor eggs (or even donor sperm and donor eggs) has tremendous advantages over classic adoption for parental bonding and child development, not to mention less cost.

There has always been a heated debate about where a child's personality and abilities come from, its environment or its genes. After counseling many hundreds of couples who have used donor sperm and having seen the results over the last 30 years, as well as having studied rather extensively the early childhood development research coming from the Harvard and the Ypsilanti early childhood projects, I have some definite views that could be of benefit to couples who are facing this issue of whether to use donor sperm (or donor eggs). It is obviously preferable emotionally to do whatever is possible to allow patients to have their own genetic baby using the husband's sperm. However, if such a solution is not at hand, the following observations should be seriously considered.

The divorce rate among couples who choose to elect donor sperm is <1%, even though the general divorce rate in our population is over 50%. This is not because the decision to have a baby by donor insemination in some way holds the marriage together. Rather, couples who wind up choosing this route have a solid relationship and a good basis of communicating with each other. Couples who have any flaws or weaknesses in their ability to communicate on tough issues usually won't choose donor insemination. Couples who do use donor insemination are a select group that have an extraordinarily solid marriage. They can deal with a potentially divisive issue and come to a common understanding that makes them both happy. So if a couple decides to use donor sperm, it is a very good sign that the marriage is going to remain solid.

Couples will frequently ask how the baby will do when its genes come half from the mother and half from some stranger. Very often they will say, "Well, at least if we go this route, as opposed to adoption, the baby will be one half ours." This outlook is a strong reason *not* to have donor insemination. My observation has been that when the husband and the wife both accept the baby as being 100% theirs, and take the view that the genetic contribution is of no significance, then the father-infant bonding is completely normal.

Although there is a controversial view held in some circles that a child's personality, intelligence, and athletic ability are basically genetically transmitted and that there is only a partial contribution from parental rearing, evidence from most donor sperm and donor egg couples, and from early childhood education projects, strongly refutes this commonly held genetic bias. In truth, the child's personality, intelligence, and even athletic skill (though not size, hair color, eye color, or body build) are overwhelmingly related to how he or she was raised in the first several years of life.

Children in the first year and a half of life are, in many respects, like parrots. They learn by copying what they see around them. A personality tends to emerge more clearly as a sense of individual identity around the age of a year and a half, when language skills first become readily apparent. The way in which a nongenetic offspring mimics his or her rearing father, regardless of genetic origin, is so striking that these parents are sometimes shocked and do double takes when a friendly neighbor (who knows nothing about the child's genetic origin) comments admiringly on how the child is the spitting image of his father. In couples who elect donor insemination, most of the time the father's bonding with the infant is no different than if it were his own "genetic" child. So donor sperm banks are crucial for the happiness of those couples with azoospermia in which no sperm can be found even in the testis.

Fertility Preservation for Oncological Reasons

Atsuko Kusuhashi and Teresa K Woodruff, Northwestern University, Chicago, IL, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Based on a 2010–2012 survey, it is estimated that approximately 40% of men and women will be diagnosed with cancer at some point during their lifetime (Howlader et al., 2017). While the incidence of cancer has increased, recent improvements in cancer treatment have led to a decrease in cancer mortality rates. In 2014, the number of cancer survivors reached an estimated 14.5 million in the United States alone (Howlader et al., 2017), and over the last 50 years, the survival rates for pediatric cancers have risen from 10% to nearly 80% (Ward et al., 2014). These cancer survivors expect to have a future that may include the decision to start a family, an important part of life for both men and women. However, recent research has shown that certain cancer treatment regimens can damage ovarian follicles in females and spermatogonia in the testis of males, leading to compromised fertility. In addition to the typical factors that affect fertility, such as age, treatment-related factors include type and cumulative dose of chemotherapy, radiation dose, and type of surgery performed (Jeruss and Woodruff, 2009; De Vos et al., 2014). The gonadotoxic effect of various chemotherapeutic agents is diverse, may involve a variety of mechanisms, and is not well understood.

Young cancer patients deliberating a potentially gonadotoxic treatment regimen may wish to preserve their fertility prior to undergoing treatment. Fertility preservation for oncological reasons—termed oncofertility—is a complex process involving the coordination of a highly skilled, multidisciplinary team. To avoid a delay in cancer treatment, the options for fertility preservation need to be discussed and performed rather quickly following diagnosis. Collaboration between oncologists and reproductive endocrinologists is necessary to understand the patient's status and goals, and determine the best fertility preservation option. This collaboration is vital, as patients must be rapidly referred from the oncology clinic to reproductive endocrinologists to undergo fertility preservation procedures, and then transferred back to oncology to begin treatment. In addition, psychosocial care providers and other resources may be brought in to help patients and their families during the decision-making process.

Histological Background of Fertility Preservation

In the 1960s, when cancer was associated with high mortality rates, little attention was paid to a patient's future fertility—the focus was on survival (Noll et al., 2013). The 1970s introduced new treatments such as megavoltage radiation therapy and combination chemotherapy that dramatically reduced the mortality rate, but also led to an increase in severe long-term side effects including cardiovascular dysfunction, pulmonary dysfunction, muscle atrophy, endocrine complications, and infertility (Nielsen et al., 2017). Long-term endocrine effects included impairment of the hypothalamus, pituitary, thyroid and gonads; decreased bone mineral density; metabolic derangements leading to obesity and/or diabetes mellitus; and infertility (Chemaitilly and Cohen, 2017). While the endocrinological effects of cancer treatment can be minimized by hormone treatments, the loss of the reproductive function is irreversible. With the increased survival rates that characterized cancer treatment in the 1970s, it became important to consider patients' future quality of life—including fertility. The health care system started to pay closer attention to the long-term effects of treatment on cancer survivors and began to improve follow-up care to patients (The National Coalition for Cancer Survivorship, 1995). Multidisciplinary teams were established to provide cancer survivors with reproductive health management options in the early 2000s (Woodruff, 2015). In 2006, the American Society of Clinical Oncology (ASCO) published a clinical practice guideline on fertility preservation (updated in 2013), which recommend that all cancer patients diagnosed during their reproductive years should be informed about potential loss of fertility, and that oncologists should be prepared to discuss fertility preservation options and/or to refer all potential patients to appropriate reproductive specialists (Loren et al., 2013).

The Impact of Cancer Treatments on Fertility

The effect of cancer treatments on fertility—here defined simply as “the ability to reproduce”—depends on the age at the time of treatment, the radiation or chemotherapy protocol, the duration of exposure, and total cumulative dose administered (Ben-Aharon and Shalgi, 2012). Most chemotherapeutic agents work by affecting cell cycle division. Therefore, cancer drugs affect the proliferation of gametes (oocytes and sperm) in the maturation stage as well as the somatic cells that support these gametes (granulosa cells in the ovary and Sertoli cells in the testes) (Blumenfeld, 2012). Radiation therapy in fields near the pelvis can directly affect the testes and ovary (Albers et al., 2005; Petersen et al., 2002). Total body irradiation given in combination with myeloablative conditioning prior to bone marrow transplantation is associated with a high risk of gonadal failure in both males and females through effects on the hypothalamus and pituitary (Vakalopoulos et al., 2015; Cohen et al., 2008). Gonadal failure may affect all aspects of reproductive health, including pubertal development, hormone production, and sexual function in adults.

Cancer Treatment and Male Infertility

For males, gonadal dysfunction is due to direct toxic effects of chemotherapy and radiation therapy on spermatogonia, the primordial germ cells that mature into sperm during spermatogenesis. The production of mature sperm from spermatogonia occurs in the testes starting at puberty. Some chemotherapies, radiation therapy, and surgery can cause damage to the testes and spermatogonia, and reduce or stop sperm production (Biedka et al., 2016). The epithelium of the testis consists of Sertoli cells and spermatogenic cells, and is particularly vulnerable. Infertility may occur immediately or within a few months after cancer treatment and can last for months or years; in some cases, infertility is permanent (Trost and Brannigan, 2012). The extent and speed of recovery of spermatogenesis following a cytotoxic incursion are dependent on the agent used and the dose received (Kandeel, 2007). Germ cell failure is common in males treated with high cumulative doses of cyclophosphamide (7500 mg/m² or more) and more than 3 months of combination alkylating agent therapy (Blumenfeld, 2012; Vakalopoulos et al., 2015). Leydig cells, the interstitial cells adjacent to the seminiferous tubules that produce testosterone, are less susceptible to cytotoxic damage; as a result, post-treatment androgen insufficiency is rare (Jeruss and Woodruff, 2009). Although the prepubertal testis does not support spermatogenesis and cannot produce mature sperm, the primordial germ cells in the prepubertal testis are nevertheless sensitive to cytotoxic drugs; therefore, chemotherapy given to prepubertal males may impair their future fertility (Vassilakopoulou et al., 2016). The spermatogonia are extremely sensitive to radiation, regardless of age. Radiation therapy can lower sperm production when it is targeted towards the testicles, pelvis, pituitary gland, and brain, as can total body radiation (Trost and Brannigan, 2012; Ogilvy-Stuart and Shalet, 1993).

The surgical management of testicular cancer can profoundly affect fertility. Removal of both testicles stops sperm production forever, while orchiectomy has been shown to decrease median sperm concentration and total sperm count (Petersen et al., 1999). In addition, surgery of the prostate, bladder, large intestine, spine, or rectum can damage the nerves and cause ejaculatory dysfunction. These operations often cause retrograde ejaculation or the backflow of semen towards the bladder, resulting in little or no sperm emission during ejaculation. Even before treatment, some cancers, such as testicular cancer and Hodgkin's lymphoma, can themselves lower sperm counts (Vakalopoulos et al., 2015).

Cancer Treatment and Female Infertility

In females, ovarian function is based on the number of oocytes in the ovary. The germ cell population reaches a maximum of 6–7 million at approximately 20 weeks of gestation when primordial follicles containing oocytes begin to form. Primordial follicles constitute a finite pool of resting ovaries in the ovary. At the time of birth, the resting follicle pool decreases to approximately 1 million due to atresia, with a further reduction to 250,000 by the time of puberty. It does not increase thereafter, gradually decreasing from birth to menopause. The age at which ovarian function is ultimately lost is based on both the size of the primordial follicle pool and the rate of depletion of this pool (Gore et al., 2014). Certain cancer drugs directly act on the ovary and affect ovarian function, causing genetic damage to growing follicles and their enclosed oocytes or ovarian failure, early menopause, and other reproductive problems. Reduction in the number of follicles by cancer treatments can lead to a premature ovarian failure, defined as menopause before the age of 41 (Wallace et al., 2005; Green et al., 2009). Chemotherapy-related amenorrhea occurs in over 90% of patients who are either treated with high-dose chemotherapies, induction therapies before bone marrow transplantation, or total body irradiation (Fleischer et al., 2011). The incidence of chemotherapy-related amenorrhea depends on the type of chemotherapy regimen used. Alkylating agents (e.g., cyclophosphamide) damage DNA and induce apoptosis through covalent binding of alkyl groups to cellular macromolecules (Hudson, 2010). Alkylating agents are highly toxic to the ovary, and the primordial ovarian follicles are particularly sensitive to these agents. The health consequences of ovarian follicle damage by cancer therapies increases with age, most likely because older females have a smaller resting follicle pool—fewer primordial oocytes—than younger females. Oocyte quality also normally declines with age, making it more difficult for older females to conceive; age compounds the negative effects of cancer treatment on reproductive function and fertility. The toxicity of chemotherapies also extends to actively growing oocytes. It is therefore recommended that patients avoid conception for at least 6 months after completion of cancer treatment (Rodriguez-Wallberg and Oktay, 2014). Cancer surgery can also reduce fertility, either through removal of or damage to the reproductive organs. Treatments such as cranial radiation can impair hypothalamic–pituitary function and indirectly impair ovarian function, resulting in sex hormone deficiency (Gonfloni et al., 2009). Radiation to the pelvis may induce uterine fibrosis, which may complicate future pregnancies (Biedka et al., 2016; Critchley and Wallace, 2005).

Fertility Preservation

Technological advances in reproductive science and medicine have made fertility preservation a viable option for patients with cancer diagnosis (Fig. 1). The standard method of fertility preservation is to cryopreserve germ cells or embryos prior to undergoing cancer treatment. Cryopreservation involves cooling cells to very low temperatures to stop all biologic activity and preserve them for future use (ASRM). The first report of sperm cryopreservation for a patient with cancer was in the 1980s and the first case of a successful pregnancy with in vitro fertilization (IVF) using cryopreserved sperm from a man diagnosed with testicular malignancy was reported in 1985 (Rowland et al., 1985). Fertility preservation is much more complicated for females, and techniques to

Fig. 1 Fertility preservation options for male and female. Fertility preservation options for post pubertal males involve collecting sperm. Sperm may be cryopreserved for later use. Investigational options for prepubertal boys include testicular tissue biopsy and cryopreservation. Oocyte or embryo cryopreservation are the most accepted approaches for female. Following cancer treatment, cryopreserved oocytes are thawed, fertilized by IVF, and transferred to the uterus as embryos.

cryopreserve oocytes, which are much larger than sperm, came about in 1986. Cryopreservation of ovarian tissue for transplantation after cancer treatment is a more recent development. Since then, fertility preservation clinical guidelines have been updated to include oocyte cryopreservation ([Ethics Committee of American Society for Reproductive Medicine, 2013](#); [Loren et al., 2013](#)), and the number of female patients undergoing fertility preservation procedures prior to cancer treatment has increased.

Fertility Preservation for Males

The testis is highly sensitive to radiation and chemotherapy at all ages; therefore, it is strongly recommended that sperm are cryopreserved prior to initiation of cancer treatment. The quality of the sperm sample and sperm DNA integrity may be compromised even after a single treatment session. Sperm cryopreservation (or “banking”) before starting cancer treatment is an established clinical option for male fertility preservation ([Ethics Committee of American Society for Reproductive Medicine, 2013](#)). Although cryopreservation is associated with a decrease in semen parameters when thawed, with advanced reproductive technologies (ART) such as IVF and intracytoplasmic sperm injection (ICSI), a low number of viable sperm is sufficient to achieve fertilization. The number of cancer survivors who have utilized ART with cryopreserved sperm are reported to be between 33% and 56%. Although the exact length of time that cryopreserved sperm remains viable is unknown, successful paternity has been demonstrated with sperm more than 21 years after cryopreservation ([Feldschuh et al., 2005](#)). When sperm collection for cryopreservation is not possible due to patient age, anatomy, or concerns about psychological impact, sperm can be removed using testicular sperm extraction (TESE) procedures ([Johnson et al., 2017](#)). For prepubertal patients who have not initiated spermatogenesis, cryopreservation of testicular tissue is another option, but remains experimental. Tissue can be obtained by multiple techniques, including testicular biopsy, and immature spermatogonia can be collected via microsurgical epididymal sperm aspiration (MESA), or TESE ([Brinster and Zimmermann, 1994](#); [Faes et al., 2013](#)). Researchers are now developing techniques to mature cryopreserved spermatogonia in vitro for use in IVF and transplant cryopreserved testicular tissue ([de Lambert et al., 2015](#)). In selected patients with testicular cancer, a partial orchiectomy has become an established option for fertility preservation.

Fertility Preservation for Females

Oocyte or embryo cryopreservation are the most accepted approaches for preservation of female fertility prior to cancer treatment. Both options require ovarian stimulation and ultrasound-guided oocyte retrieval for either freezing for later use or for IVF. Following cancer treatment, cryopreserved oocytes are thawed, fertilized by IVF, and transferred to the uterus as embryos. Oocyte

cryopreservation is particularly important for females who do not have a partner at the time of cryopreservation (Loren et al., 2013). In most countries, women who have a partner at the time of oocyte retrieval choose to create embryos for cryopreservation. In some countries, women can use sperm donors if they do not have a partner. Because ovarian stimulation with gonadotropins is needed to obtain more than one mature oocyte per cycle for cryopreservation of oocytes or IVF (Rodriguez-Wallberg and Oktay, 2014), this option is possible only if cancer treatment can be delayed and in women who do not have hormone-sensitive cancers, such as certain breast cancers (Blumenfeld, 2012). Ovarian tissue cryopreservation (OTC) is another fertility preservation option for female patients who need to start cancer treatment immediately or have hormone-sensitive cancers, or for pediatric cancer patients (Meirow et al., 1999; Fleischer et al., 2011) who cannot undergo ovarian stimulation. In 2004, the first live birth after transplantation of frozen-thawed ovarian cortex was reported by a Belgian group (Donnez et al., 2004). Strips of ovarian cortical tissue were cryopreserved prior to cancer treatment; the patient subsequently experienced ovarian failure and 6 years after treatment the frozen-thawed cortical strips were transplanted into the peritoneal window beneath the hilum of the inactive ovary. A follicle that had physiologically matured in the transplanted ovarian tissue was collected for IVF (Donnez et al., 2004). Although OTC is still considered an experimental technique, 60 live births after transplantation of cryopreserved ovarian tissue have been reported as of 2016 (Meirow et al., 1999). For patients with blood-borne malignancies or ovarian cancer, there is a potential risk of reintroducing cancer cells within the cryopreserved ovarian cortex; this risk must be taken into account before ovarian tissue transplantation.

New approaches in gynecologic oncologic surgery are being developed with the goal of preserving reproductive organ function without compromising survival. Patients with well-differentiated, low-grade, early-stage tumors or tumors with low malignancy are potential candidates for these procedures (Wallberg et al., 2009). Young women presenting with borderline ovarian tumors may be offered a single oophorectomy (Mangili et al., 2016). Another established surgical procedure for fertility preservation in young female patients is radical trachelectomy for early-stage invasive cervical cancer (Tomao et al., 2016).

Pediatric Fertility Preservation

Children with cancer suffer both short- and long-term side effects of cancer and its treatment, including future infertility (Meirow et al., 1999). Established methods of fertility preservation such as sperm cryopreservation in adult males and embryo and oocyte cryopreservation in adult females are not possible in prepubertal males and females because of their gonadal immaturity (Ben-Aharon and Shalgi, 2012) (Table 1). Puberty affects the growth and maturation of the gonads, and is associated with the initiation of spermatogenesis in male and follicular growth and ovulation in females. As in adults, gonadal function may be affected by cancer treatment in children, and may affect not only future fertility but also the growth and maturation of the gonads during juvenile development. In prepubertal patients, failure of pubertal development may be the first sign of gonadal failure (Thibaud et al., 1998). One challenge in fertility preservation for pediatric patients is that parents may feel uncertain about making fertility-related decisions on behalf of their child (Loren et al., 2013). The mean age of diagnosis of pediatric cancer patients is 6 years; in such situations, patients and their families are asked to consider future fertility. Several studies have confirmed that adult survivors of pediatric cancer wish they had been given more information and options about fertility at the time of diagnosis (Cvancarova et al., 2009). Therefore, discussing fertility preservation is critical for pediatric cancer patients' long-term quality of life.

Management

In most cases, decisions about fertility preservation need to be made before cancer treatment begins (Table 2). Since post-therapy recovery of gonadal function is unpredictable, it is important to inform patients facing potential treatment-related infertility of this possible side effect and all the options that are available to prevent it. When patients are counseled on fertility preservation for oncological reasons, they usually are still processing the life-changing cancer diagnosis and may be under pressure to initiate cancer treatment. Decision making about preserving fertility can add to the emotional burden at the time of diagnosis, but fertility preservation

Although patients have just received a life-changing cancer diagnosis, it is important to know the potential treatment-related infertility and all the options that are available to prevent it.

can also provide hope for a future. Resources and tools have been developed to help the multidisciplinary providers involved in fertility preservation in the oncological setting. Collaboration between oncologists and reproductive medicine providers is necessary for patients to receive timely access to fertility preservation options after a cancer diagnosis. In 2013, clinical guidelines changed the label of who is responsible for discussing fertility preservation by relabeling “oncologist” as “health care provider,” and extending this label to medical oncologists, radiation oncologists, gynecologic oncologists, urologists, hematologists, pediatric oncologists, and surgeons, as well as nurses, social workers and psychologists (Ethics Committee of American Society for Reproductive Medicine, 2013; Loren et al., 2013). Social workers and psychologists can be particularly helpful when a patient is distressed about potential infertility as a result of cancer or its treatment.

Other family building options after cancer include the use of gestational carriers, embryo donation, egg or sperm donation, and adoption (Loren et al., 2013). Focusing on the potential consequences of cancer treatment and infertility, and finding solutions to preserve or restore fertility and reproductive function, has become its own field of study. Advances in oncofertility research continue to improve and expand fertility preservation options for cancer survivors and focus on finding better ways to protect oocytes from the toxic effects of cancer treatments (Kim et al., 2016). Fertility preservation gives hope to cancer patients who will survive their disease by offering the option of preserving their fertility (Woodruff, 2015).

Fertility Preservation in Women for Social Reasons

The Social Context of Fertility Preservation in Women

Age of Childbearing Is Increasing in High-Income Countries

In most high-income countries, the age of childbearing is increasing. Many factors contribute to this including access to effective contraception and safe legalized abortion; life course changes including women's increased education and labor market participation; postponement of partnership formation; and structural factors including the increased cost of housing, economic uncertainty and the absence of supportive family policies such as paid maternity leave, flexible working arrangements, and access to high quality and affordable child care.

As women age their fertility declines. The monthly chance of pregnancy for couples where the woman is 35 years or younger is about 20% and 80%–90% achieve a pregnancy within 12 months. By age 40 the monthly chance has dropped to 5% and only 50% of couples conceive within 12 months. Age-related fertility decline is a cause of involuntary childlessness or having fewer children than planned. To overcome age-related infertility some people use assisted reproductive technology (ART) to conceive. However, as with spontaneous conception, the chance of conceiving with ART decreases with increasing female age and ART pregnancies are rare among women in their forties. To guard against age-related infertility women who plan to have children at an age when their fertility is likely to have declined can freeze their eggs (oocyte cryopreservation) when they are younger and use them in an assisted reproductive technology (ART) procedure when the time for childbearing is right for them.

Social Acceptability of Fertility Preservation for Nonmedical Reasons

Existing research and public discourse relating to childbearing focus almost exclusively on women and declining fertility rates are often portrayed as being the result of women delaying childbearing to pursue other life goals such as a career and travel. The term 'social egg freezing' is often used in the professional literature and in the media to describe women who freeze their eggs to avoid age-related infertility. This term implies that women make self-interested decisions about timing of childbearing. However, research indicates that the lack of a partner willing to commit to partnership and parenthood is the main reason for the decision to freeze eggs to postpone childbearing (Pritchard et al., 2017). Therefore, 'non-medical egg freezing' may be a more accurate and less judgemental term to describe fertility preservation to prevent age-related infertility.

Emerging research indicates that fertility preservation is becoming a socially acceptable option for women who anticipate age-related infertility and is likely to be used by an increasing number of women. Data from surveys show that most Swedish women aged 30–39 have a positive attitude towards egg freezing for non-medical reasons (Wennberg et al., 2016); about one in three women of reproductive age in Belgium would consider oocyte cryopreservation to extend their reproductive life (Stoop et al., 2011); and, among childless women aged 28–35 years who completed an online survey, the intention to freeze eggs was associated with feeling susceptible to infertility, considering egg freezing useful to achieve parenthood, and expecting to have children at a later age (ter Keurst et al., 2016). Since 2014 large companies such as Apple and Facebook have covered the cost of oocyte cryopreservation for their female employees. Some argue that rather than an altruistic gesture, this is most likely for the commercial benefit to the company of not having childbearing interrupt young talented women's careers.

Who Freezes Eggs for Nonmedical Reasons and Why?

Women who electively freeze their eggs are predominantly aged in their late thirties, well educated, socioeconomically advantaged, and single. Since there is considerable cost associated with egg freezing for non-medical reasons, being financially well-resourced is likely a pre-requisite for undergoing the procedure.

Stated reasons for freezing eggs include not having a partner with whom to have children; having a partner who is unwilling to be a father; wanting time to prepare financially, emotionally, and socially for single parenthood; investing in the future; and using egg freezing as an insurance against not finding a partner while still fertile (Pritchard et al., 2017).

Views on Benefits and Risks of Egg Freezing for Nonmedical Reasons

Opinions vary about the potential benefits and risks of fertility preservation for non-medical reasons. Some argue that it helps women by adding to their reproductive choices and allowing them to extend their reproductive lifespan. This in turn gives them more time to find a suitable partner and fulfill other life goals before having children and reduces their risk of age-related chromosomal abnormalities and miscarriage (Goold and Savulescu, 2009). Using their mathematical model, Devine et al. (2015) contend that for women who plan to delay childbearing until age 40 years, egg freezing at a younger age is more cost-effective than using ART at age 40. Stated potential risks of fertility preservation include that it might encourage women to delay childbearing beyond the natural reproductive lifespan and that this increases the risk of adverse pregnancy outcomes for both mother and baby (Radon et al., 2015). Others are concerned that women are 'misled to believe that the reproductive fountain

of youth is obtainable by freezing their eggs' (Schattman, 2016). Some make the case that, rather than encouraging egg freezing to avoid age-related infertility, family-friendly social policies that support people to have children during their most fertile years would be more helpful (Martin, 2017; Mertes, 2015).

Medical Aspects of Fertility Preservation in Women

What Egg Freezing Involves

Egg freezing has been used for several decades to preserve fertility in women who need cancer treatment which can diminish fertility. Freezing techniques have improved over time and with vitrification, the currently most commonly used technique, frozen eggs used in ART have a similar potential to result in a live birth as 'fresh' eggs (Argyle et al., 2016). With improved efficiency, egg freezing is advertised as an 'insurance' against age-related fertility decline and the number of healthy women who freeze their eggs to guard against future involuntary childlessness is increasing (Domingo et al., 2016).

The process of egg freezing involves a course of hormone injections to stimulate the ovaries to produce multiple eggs. Egg maturation is monitored with ultrasound and blood tests and when the eggs are mature they are retrieved in a transvaginal ultrasound-guided procedure under light anesthetic. The retrieved eggs are stored in liquid nitrogen until the woman returns to use them. At that time, they are thawed and inseminated with sperm from the woman's partner or a donor. If healthy embryos develop, one (sometimes two) is transferred to the uterus and any remaining embryos can be frozen for later use.

The Chance of a Live Birth After Egg Freezing

The two most important factors that determine the chance of having a baby from frozen eggs are the woman's age when the eggs are frozen and the number of eggs that are stored. The number and quality of eggs available for freezing is important because in every step there is a risk that some are lost. Of the eggs that are retrieved, some may not be suitable for freezing, some may not survive the freezing and thawing processes, and some may not fertilize or develop into normal embryos. Of the embryos that are transferred, only some will result in a pregnancy, and some pregnancies will miscarry.

The number and quality of the eggs that develop when the ovaries are stimulated decline with increasing age. A woman in her early thirties might have 15–20 eggs available for freezing after the hormone stimulation but for women in their late thirties and early forties the number is usually much lower. Also, as women age they are more likely to have eggs with chromosomal abnormalities. It is estimated freezing 10 eggs at age 35 years or younger gives women a 69% chance of having a live birth. This drops to 50% for women aged 37 and 30% for women aged 40 at the time of egg freezing (Goldman et al., 2017).

Using the Frozen Eggs

Egg freezing for non-medical reasons is a relatively new phenomenon and little is currently known about the reproductive outcomes of women who freeze their eggs. The limited existing evidence suggests that the number of women returning to use their eggs is still low (Cobo et al., 2016; Shenfield et al., 2017) and that most pregnancies that occur after egg freezing are a result of natural conception or an ART procedure using 'fresh' eggs (Hodes-Wertz et al., 2013; Hammarberg et al., 2017a). A study of 96 women who had stored their eggs found that only six had returned to use them, three of whom had had a baby as a result. Another 12 women had conceived naturally and six had conceived after an ART procedure using 'fresh' eggs. That almost half of the respondents had stored oocytes in the two years preceding the survey may, in part, explain why so few had used them. The main reasons for not using the stored eggs were not wanting to be a single parent, preferring to conceive naturally, and not wanting to use a sperm donor which indicates that women were still hoping to find a male partner willing to commit to parenthood (Hammarberg et al., 2017a).

Medical Risks of Egg Freezing

A small proportion of women have an excessive response to the fertility drugs that are used to stimulate the ovaries. In rare cases, this can cause ovarian hyperstimulation syndrome (OHSS), a potentially serious condition. Bleeding and infection are very rare complications of the egg retrieval procedure.

Egg freezing is still a relatively recent technology and the long-term health of babies born as a result is not known. However, it is reassuring that their health at birth appears to be similar to that of other children (Cobo et al., 2014).

Cost of Fertility Preservation

The cost of egg freezing varies between countries and between clinics. Around US\$10,000 is commonly quoted for hormone stimulation, egg retrieval and egg freezing. Older women often need more than one treatment cycle to have the 10–15 eggs needed to provide a reasonable chance of having a baby as a result. In addition, annual storage fees of US\$300–500 are common and when women return to use their eggs they are charged for the cost of thawing the eggs, fertilization of the eggs with partner or donor sperm, and embryo transfer.

Psychological Aspects of Fertility Preservation in Women

Information Needs of Women Who Freeze Eggs for Nonmedical Reasons

Fertility preservation is often promoted as an insurance against future childlessness. However, there is no guarantee that a live birth will result from frozen eggs. Most data relating to the chance of success using frozen eggs stem from egg donation programs. Because egg donors are on average younger than women who electively freeze eggs it is questionable whether data from egg donation programs can be extrapolated to women who freeze oocytes for non-medical reasons.

To make informed decisions about fertility preservation women need accurate and realistic information about the likelihood of a live birth; the cost of retrieval, storage, and later use of the eggs; and the known and potential risks of the procedure for the woman herself and any future children. While acknowledging that egg freezing should no longer be regarded as experimental, in 2013 the American Society for Reproductive Medicine (ASRM) cautioned that ‘data on the safety, efficacy, cost-effectiveness, and emotional risks of elective oocyte cryopreservation are insufficient to recommend elective oocyte cryopreservation’ and that ‘marketing this technology for the purpose of deferring childbearing may give women false hope and encourage women to delay childbearing’ (ASRM, 2013). But, even if comprehensive information is provided, women may still over-estimate the potential of frozen eggs to result in a birth. A qualitative study of women who had stored their eggs because they wanted to share parenthood with a future partner rather than be a single parent found that they dismissed information about limited success rates and potential risks and were overly optimistic about their own chance of success. And, although the women found the procedure very costly, they were willing to invest their money to increase their chances for shared parenthood (de Groot et al., 2016).

Psychological Needs of Women Who Freeze Eggs for Nonmedical Reasons

While data about the safety and efficacy frozen eggs is accumulating, evidence about the psychological needs of women who contemplate fertility preservation is limited. Nevertheless, based on evidence about optimal care in the context of ART, women who contemplate or undergo fertility preservation for non-medical reasons are likely to benefit from continuity of care, staff who understand the emotional impact of egg freezing, access to understandable and personally relevant treatment information, and specialized psychosocial care being offered before, during and after treatment.

In addition to the psychological difficulties inherent in undergoing ART treatment there are specific challenges that may confront women who freeze eggs for non-medical reasons that clinic staff need to be aware of and prepare women for. There are many reasons why eggs may remain unused including the woman conceiving naturally or with ART with ‘fresh’ eggs, not finding a partner and not wanting to be a single mother, or feeling too old to become a mother. If the eggs are not used women need to decide whether to donate them to another woman or discard them. Such a decision can be difficult, particularly for women who still want children but who are unable to through their circumstances. For women who decide to use the eggs and donor sperm to try to have a child, the complexities of donor conception and single parenthood need to be explored. Lastly, women who return to use their eggs may not be successful and regret spending time, effort and financial resources on freezing eggs. Also, their opportunities for experiencing motherhood may then be exhausted and they may grieve for the children they wanted but were unable to have.

Men’s Role in Reproductive Decision Making

The few studies that have gauged the reasons for freezing eggs to postpone childbearing report that most commonly it is not having a partner with whom to share parenting. Research shows that although men almost universally value parenthood, want and expect to become fathers, and aspire to have at least two children, they have inadequate knowledge about the limitations of female and male fertility and overestimate the chance of spontaneous and assisted conception (Hammarberg et al., 2017b). This may lead to unfulfilled parenthood aspirations for women and men. Childbearing and parenting are shared endeavors and better understanding of men’s contribution to childbearing decisions and the factors that influence this are crucial to informing policy and public education responses. Government policies and public education strategies aimed to support childbearing during the most fertile years are needed to reduce the personal and societal cost of infertility and ART use, including fertility preservation, and allow people to fulfill their parenthood goals.

CLINICAL STRATEGIES

The Ovulation: Triggering Ovulation with hCG Versus GnRH-Agonist

Mustafa Bahceci and Fazilet Kubra Boynukalin, Bahceci Fulya IVF Center, Istanbul, Turkey

© 2018 Elsevier Inc. All rights reserved.

Molecular Similarity and Differences between hCG and LH

Pulsatile GnRH secretion in a critical range for frequency and amplitude is necessary for normal ovulatory function. GnRH has three positive action on gonadotropins; (i) synthesis and storage (ii) activation, and (iii) immediate secretion (Hoff et al., 1983). In normal menstrual cycle, exponential increase of estradiol secretion and small but distinct rise in progesterone levels in late follicular phase, LH levels increases 10-fold over 2–3 days while FSH levels increases fourfold. LH surge is mandatory for final maturation of the oocyte and rupture of the follicle. It is the critical component of normal menstrual cycle (Itskovitz et al., 1991).

LH and hCG have the same α -subunits, their main differences involve the sequence of the β -subunit. They share the same receptor, LH/CGR. LH/CGR, is expressed in different sites of the reproductive tract and extra-gonadal tissues and expression of this receptor is necessary for promoting oocyte maturation, fertilization, implantation, and early embryo development (Weissman et al., 1996). In consequence, hCG has been administered successfully for many decades for the endogenous LH surge to induce final oocyte maturation.

The biggest difference between LH and hCG is that hCG, has a circulating half-life of 37 h, while LH, has a circulating half-life of just 25–30 min (Cole, 2010). Following intramuscular (IM) administration of hCG has a slower plasma metabolic clearance consists of a rapid phase in the first 5–9 and a slower phase in the first 1–1.3 days after administration. Besides this difference, hCG demonstrates a stronger LH/CGR receptor binding affinity, probably due to differences in the carbohydrate moiety, and is much more potent (roughly six to eight times greater) than LH (Theofanakis et al., 2017).

Luteal Phase Physiology; Difference Between hCG Trigger and GnRH-a Trigger for Final Oocyte Maturation Trigger

In the normal menstrual cycle, the midcycle LH and FSH surge is a complex event which takes apart in late follicular phase by exponentially increasing estrogen concentrations in combination with a small, but distinct, rise in P. Exogenous FSH administration either for COH in IVF or for the treatment of anovulation, the timing of the endogenous LH surge is frequently interrupted. Therefore, exogenous hCG has been used for decades to replace endogenous LH during FSH stimulation protocols to induce ovulation, final oocyte maturation, and corpus luteum formation. In COS cycles triggered with hCG, endogenous LH secretion is negatively affected by supra-physiological steroid levels (estradiol and progesterone) and cause a disruption of the luteal phase. The physiological mid-cycle surge of LH and FSH last 48 h after its onset however the hCG-mediated LH activity extends several days into the luteal phase. The supraphysiologic hCG mediated LH activity stimulates multiple corpus luteum activity which causes high serum progesterone and estradiol. This hormonal milieu decreases the endogenous LH secretion by pituitary. Although large amount of granulosa cells being removed during oocyte pick-up procedure, hCG mediated corpus luteum activity promotes uterus for implantation. In the process of implantation, hCG levels start decreasing and endogenous progesterone productions are negatively influenced. Besides this, low endogenous LH levels leads to disruption of the luteal phase, causes requirement for exogenous progesterone supplementation is mandatory until the increase in endogenous hCG production from implanting embryo for luteal phase support (LPS) (Fauser and Devroey, 2003).

The synthesis of GnRH-a was succeeded in late 1970s and increased receptor affinity and decreased degradations was led with alterations or deletions of in amino acid at position 6 and 10. These changes resulted 100–200 times greater GnRH activity releasing LH and FSH from the pituitary (Casper, 2015). There are different GnRH-a commercially available leuprolide, buserolin, and triptoreline. There is no consensus on the type and dosage for ovulation trigger.

Gn-RHa trigger was first analyzed in 8 cases of timed intercourse or IUI cycles and ovulation was determined by follicle collapse on USG. The characteristics of luteal phase was seem to be similar to spontaneous ovulation (Lanzone et al., 1989). The use of GnRH-a trigger in IVF cycles was first reported in 1990 and midcycle LH surge was revealed. Mature oocytes were retrieved and pregnancy was resulted after luteal support with progesterone (Bentick et al., 1990). The first randomized study comparing the single bolus of 500 mg of leuprolide acetate to 5000 international units (IU) of hCG as the trigger for follicular and oocyte maturation described the difference between luteal phase. The serum LH and FSH levels were elevated for 34 h after GnRH-a administration, in contrast hCG administration resulted serum hCG levels were detectable till 6 days later without any rise in FSH levels. The results of this study reported that the release of administration of GnRH-a in an IVF cycle was a good alternative to complete the final stage of follicular maturation, resulting in the retrieval of fertilized oocytes, with normal embryo development

to hCG (Gonen et al., 1990). In 1992, a larger study in IVF cycles were randomized to receive 5000 IU of hCG, or 500 mg of leuprolide acetate, to trigger final follicular maturation. The luteal phase estradiol and progesterone levels were significantly lower and clinically short luteal phases, despite vaginal P administration was detected in GnRH-a triggered cycles (Segal and Casper, 1992).

In a randomized multicenter study, the efficacies of two different GnRH-a were compared with that of hCG for triggering final stages of oocyte maturation after COS for IVF using antagonist protocol. LH peak was resulted 4 h after both triptorelin and leuporelin administration. Within administration of GnRH-a 24 h LH and FSH levels were significantly higher in both GnRH agonist groups compared with hCG. Luteal phase progesterone and estradiol were significantly elevated in the hCG group. The mechanism under this circumstance is thought to be; GnRH-a trigger for final oocyte maturation causes a direct pituitary down-regulation and therefore, the remaining corpora lutea lack LH-stimulus and are not capable to sustain progesterone production for the luteal phase. The mean numbers of oocytes retrieved, the percentages of metaphase II oocytes and fertilization rates were similar in the triptorelin, leuporelin, and hCG group (Fauser et al., 2002). These findings support the effective induction of final oocyte maturation in both GnRH-a groups.

The spontaneous LH-surge in a natural cycle is characterized by an ascending phase of approximately 4 h, a peak plateau of 20 h, and a descending phase of 20 h whereas the GnRH-a-induced LH/FSH surge consists of two phases; a short ascending phase lasting > 4 h and a long descending phase lasting > 20 h and has a total duration between 24 and 36 h. The supraphysiologic luteal steroid levels produced by multiple corpora lutea, which directly inhibit LH secretion from the pituitary is the most important reason. In addition, GnRH-a triggering leads to a significant shorter in the luteal phase compared with hCG triggering. Most important reason for the abnormal luteal phase is early luteal LH levels remain significantly lower as compared to hCG triggering (Humaidan et al., 2005). GnRH-a trigger in oocyte donors was evaluated in a randomized trial and the mean duration of the nonsupplemented luteal phase after GnRH-a trigger in was as short as 4 days, compared with 13 days after hCG trigger, suggesting a markedly defective luteal function (Acevedo et al., 2006).

Molecular based studies demonstrated that the human ovary is a target for GnRH (Nathwani et al., 2000). Cultured granulosa cells, the GnRH agonist was revealed to mobilize Ca, activate mitogen protein kinases, increase c-fos mRNA expression, and decrease its steroidogenic capacity (Kang et al., 2001; Brus et al., 1997; Minaretzis et al., 1995; Hori et al., 1998). It was supposed that luteolysis would ultimately be due to the capacity of the GnRH agonist to initiate the intracellular cascade that drives the cell to programmed cell death or apoptosis.

GnRH-agonist for final oocyte maturation reported a very poor reproductive outcome due to the severe luteolysis and it was assumed that the extend of the induced luteolysis cannot be counterbalanced by using standard luteal phase support with only progesterone administration. However, lately several case reports demonstrate that luteolysis after GnRH-agonist trigger is not complete and varies, indicating distinct differences among patients. In a more recent study; it was reported that longer stimulation duration as well as a higher level of progesterone on the day of final oocyte maturation and more retrieved oocytes will result in higher levels of progesterone 48 h after oocyte retrieval and concluded that luteolysis after GnRH-agonist trigger is patient-specific and also luteal phase support requires individualization (Lawrenz et al., 2017).

Clinical Outcome; Safety and Efficacy of GnRH-a Triggered and hCG Triggered Cycles

During the last decade of the twentieth century, intensive pharmaceutical efforts reached the target of producing GnRH antagonists with proven clinical activity and few side effects. The worldwide common use of GnRH antagonist protocols has allowed the widespread use of GnRH-a for triggering final follicular maturation. It is accepted to be the major way to prevent ovarian hyperstimulation syndrome (OHSS).

OHSS is a potential morbidity and mortality undergoing fertility treatment, according to the most recent report by the European Society of Human Reproduction and Embryology (ESHRE) (Kupka et al., 2014). The predictive effect of GnRH-a trigger is due to the shorter half-life of the endogenously secreted LH compared to the long acting LH activity after an hCG trigger, which results in a defective corpus luteum formation (Engmann et al., 2008). Not only the shorter half-life, also follicular fluid composition VEGF, which may relate to reduction in the risk of OHSS, differed significantly between the GnRH-a and hCG trigger. Decrease in the release of VEGF is a major factor for the preventive effect of OHSS (Humaidan et al., 2011).

It has been reported that GnRH-a trigger has a higher oocyte maturation rate (Imoedemhe et al., 1991). EGF-like peptides have been shown to be potent mediators of oocyte maturation. Follicular fluid levels of amphiregulin (AR) and EGF-like peptide following GnRH-a trigger was reported to be closer to the natural cycle levels. The authors suggested that a bolus of hCG represented a supra-physiological signal for oocyte maturation compared with that of the natural cycle and GnRH-a trigger, and that this supra-physiological signal might have negative impacts on the oocytes and embryos (Humaidan et al., 2011).

The transcriptome of the somatic cells of the follicle was explored in patients who had final oocyte maturation with either hCG or GnRH-a and showed significant functional differences which may led to decreased OHSS and higher oocyte maturation rates (Borgbo et al., 2013).

Few studies have addressed failed trigger with the use of GnRH agonists. The highest reported failure rate for GnRH agonist trigger is 3.5% (Castillo et al., 2012). In a more recent study, risk factors for inadequate trigger response was analyzed. Two percent of patients triggered with GnRH agonist had an inadequate response and were retriggered with hCG. Low body mass index, low baseline LH, and higher total dosage of gonadotropins required for stimulation were associated with an increased risk of having an inadequate response to the GnRH agonist trigger (Chang et al., 2016).

The reproductive outcome of oocytes and embryos that are obtained from GnRH-a trigger in oocyte donation programs are good either fresh or frozen-thawed cycles (Acevedo et al., 2006; Bodri et al., 2009; Griesinger et al., 2007). The earlier studies suggested that high level hCG concentrations mediated an exaggerated intrafollicular shift in steroids from androgens, estradiol and progesterone and causes a detrimental effect on embryo development (Fanchin et al., 2001). Morphokinetic characteristics of embryos was analyzed in a retrospective cohort study and embryos from cycles GnRH-a triggered cleaved faster than embryos from hCG triggered cycles but the embryo quality was not significantly different (Muñoz et al., 2013).

Endometrial GnRH receptor expression was demonstrated by some studies and mid-luteal bolus of GnRH-a resulted improvement in implantation rates. It was hypothesized that GnRH receptor mediated IL-1b and VEGF production in endometrium improves implantation rates (Schachter et al., 2008). In contrast some studies reported a potential negative impact of hCG on endometrial receptivity. It was suggested precocious exposure of the endometrium to hCG, outside the timing of normal endometrial-embryonic communication, down-regulates the endometrial epithelial LHCG-R (Evans and Salamonsen, 2013). Also, after hCG trigger P levels peak significantly earlier than during natural cycle which may lead to impair endometrial receptivity.

The impaired luteal phase after GnRH-a trigger, is the major draw back in fresh cycles. The mean mid-luteal LH level of the natural cycle is nearly 4 times greater than GnRH-a trigger (6 IU/mL vs. 1.5 IU/mL). Lower LH levels are leading insufficient luteal phase and causes early luteolysis at the end implantation failure or early pregnancy loss occurs in fresh ET cycles using a standard LPS.

The first published Cochrane review comparing GnRH-a versus hCG trigger was published in 2010 and concluded that 'GnRH agonists should not be routinely used as a final oocyte maturation trigger in fresh autologous cycles because of lowered live birth rates and ongoing pregnancy rates' (Youssef et al., 2010). A more recent updated Cochrane review on GnRH-a trigger reached the same general conclusions of the previous review and stated that "GnRH agonist triggers significantly reduce the risk of ovarian hyperstimulation, but also lower the chance of pregnancy in fresh autologous IVF-ICSI treatment cycles compared with HCG. GnRH agonist use as an oocyte maturation trigger could be useful for women who choose to avoid fresh transfers (for whatever reason), women who donate oocytes to recipients or women who wish to freeze their eggs for later use in the context of fertility preservation" (Youssef et al., 2014). The last Cochrane analysis luteal phase support differs between studies included. The Cochrane review included a Forest plot in which a stratification for LPS with and without LH activity was performed. Importantly, in this analysis there was no significant difference in ongoing pregnancy rates between GnRH-a with modified LPS and hCG trigger, OR 0.89 (95% CI 0.65–1.21).

The optimal type of luteal phase support after GnRH-a trigger followed by fresh transfer is still subject to research and has not reached its final form. The physiological advantage of the GnRH-a trigger concept is clear but the defective luteal phase is a major concern. The early luteal phase support individualizations should be answered.

There are two different strategies for effective luteal phase support in GnRH-a triggered fresh cycles; (i) corpus luteum rescue (European Approach) and (ii) exogenous steroid support (American Approach).

Corpus Luteum Rescue

Today, minimum hCG dose needed to rescue the corpora lutea until the hCG produced by the implanting embryo covers the luteal LH activity deficiency without increasing the risk of OHSS does not known exactly.

In a randomized pilot study low dose hCG (1,500 IU) was administered at either 12 h or 35 h after GnRH-a trigger, followed by a standard LPS and compared with hCG trigger. Higher mid-luteal P levels and better pregnancy rates were reported in the 35 h group compared with the 12 h group. Importantly, no differences in pregnancy outcomes were seen between the GnRH-a trigger 35 h hCG group and hCG group. This results suggested that a refractory period may occur after the initial GnRH-a trigger, during which human granulosa cells do not respond to subsequent LH-like exogenous stimulation. This pilot study included 45 normal responder patients and suggested that the ideal timing of the 1500 IU hCG rescue bolus after GnRH-a trigger seemed to be at 35 h after trigger—immediately after oocyte retrieval (Humaidan et al., 2006).

In a retrospective analysis including high risk for OHSS reported that GnRH agonist trigger combined with 1500 IU hCG at the time of oocyte retrieval and subsequent estradiol and progesterone replacement in OHSS high-risk patients can facilitate fresh embryo transfer with high clinical pregnancy rates and a low risk of severe OHSS (Iodromiti et al., 2013).

A new protocol was initially explored prospectively in a small group of 12 OHSS high-risk patients, having 25 or more follicles > 11 mm. Patients were administered a bolus of 1,500 IU hCG following GnRH-a trigger, 2 h after the oocyte retrieval, resulting reassuring results as regards live birth rate (50%) and OHSS reduction (Humaidan, 2009). A large randomized controlled trial including a total of 302 patients was performed to corroborate these findings. Until now, this study is the largest comparing hCG triggering with 10,000 IU hCG with GnRH-a triggering supplemented with a bolus of 1500 IU hCG on the day of oocyte retrieval. This study reported a nonsignificant difference in live birth rates between GnRH-a triggering and hCG triggering of 24% and 31%, respectively, per patient started. No OHSS case was seen in the group of patients who had GnRH-a trigger final oocyte maturation, compared with 2% in the hCG group (Humaidan et al., 2010).

Two RCTs including a total of 390 patients compared GnRH-a trigger with hCG trigger, with the use of hCG supplementation. The primary outcome of the study was OHSS incidence in the group at risk of OHSS and secondary outcome was pregnancy rates. Thus, in patients with 14 follicles > 11 mm, who were considered to be at low OHSS risk, an additional bolus of 1500 IU hCG was administered on the day of oocyte retrieval + 5, in addition to the 35-h dose. Patients with 15–25 follicles > 11 mm received a single bolus of 1500 IU hCG at 35 h only. All patients were supplemented with standard luteal phase support. Patients with > 25 follicles were excluded from the study in an effort to set an upper cutoff level for the risk of OHSS development after fresh transfer. No OHSS was seen in the OHSS high-risk group (15–25 follicles) triggered with GnRH-a, versus 3% for those triggered with hCG. In contrast, two patients in the group considered to be at low OHSS risk (< 14 follicles) developed late-onset moderate OHSS (Humaidan et al.,

2013). Further fine-tuning was necessary to find the minimal dose of hCG administered to secure optimal pregnancy rates without increasing the OHSS incidence in the OHSS low-risk group.

rLH administration was used after GnRHa trigger combined with a standard LPS in a small proof-of-concept study. A total of 17 patients in the control group had a trigger with 6,500 IU hCG followed by a standard LPS. In the study group a total of 18 patients received a GnRHa trigger followed by a total of six doses of 300 IU rLH administered every second day during the luteal phase combined with a standard LPS. All patients underwent elective single blastocyst transfer. Similar implantation rates (25.0% vs. 26.7%, respectively) were seen in the two groups, and no OHSS case was reported in this study, consisting of only normal responder patients (Papanikolaou et al., 2011).

The exogenous steroid free luteal phase in GnRHa triggered IVF/ICSI cycles was explored in a proof of concept trial in which 93 normal responder patients were randomized to either GnRHa trigger (two study groups) or hCG trigger (control group). In both study groups, the luteal phase was supported with a daily subcutaneous bolus of 125 IU hCG until the pregnancy test was performed. No other LPS was used. In the hCG trigger control group a standard LPS, consisting of vaginally administered micronized P was given until the day of the pregnancy test. The authors reported no significant differences in neither pregnancy rates nor early pregnancy loss rates between groups. Four moderate late onset OHSS were seen in the control group (6%) and one in each of the study groups (3%) (Bar-Hava et al., 2016).

Exogenous Steroid Support

Luteal phase after GnRHa trigger with the use of luteal phase support similar to that used after hCG trigger reported poor results (Humaidan et al., 2005).

In a randomized controlled trial that all of the patients received 50 mg intramuscular (IM) progesterone (P) daily and three 0.1-mg estradiol (E2) transdermal patches every other day starting on the day after oocyte retrieval starting the evening after oocyte retrieval and continued until 10 weeks' gestation after GnRHa trigger with an excellent ongoing pregnancy rate of 53.3%. Serial serum E2 and P were measured on the day of embryo transfer, 1 week after oocyte retrieval, and weekly thereafter. The dose of transdermal E2 patches was increased, to a maximum of four 0.1-mg patches every other day, and/or addition of oral micronized E2 to maintain the serum E2 level > 200 pg/mL. The IM P dose was also increased, if necessary, to a maximum of 75 mg daily and/or addition of micronized vaginal P to maintain serum P level > 20 ng/mL (Engmann et al., 2008). Similar intensive luteal support protocol have also reported favorable results with fresh transfers (liodromiti et al., 2013).

In 2011, Devroey et al. reported a strategy to obtain an OHSS-Free Clinic, the segmentation concept. It consists of optimization of the ovarian stimulation, including GnRH agonist triggering in a GnRH antagonist cycle (segment A). Segment B then consists of optimum cryopreservation methods for oocyte or embryo vitrification. Segment C includes embryo replacement in a receptive, nonstimulated endometrium in a natural cycle or with artificial endometrial preparation (Devroey et al., 2011). The potential advantage of this method is that it provides a more physiologic environment in which ET can occur; this advantage could lead to better pregnancy rates and decreased maternal and perinatal morbidity (Barnhart, 2014).

In a retrospective cohort study, congenital anomalies, obstetrical complications, and neonatal complications in antagonist cycles where either GnRH-a or hCG was used for final oocyte maturation. There were no significant differences in the rate of congenital anomalies between GnRHa and hCG trigger (6.6% vs. 9.2%). There were also no differences in the maternal complications (27.6% vs. 20.8%) or neonatal complications (19.7% vs. 20.0%) between the GnRHa trigger and hCG trigger groups (Budinetz et al., 2014).

Conclusion

GnRH-a trigger has physiological advantages over HCG trigger and seems to be patient friendly. The major drawback of GnRH-a trigger is the most optimal luteal-phase support after GnRHa trigger is not clear and still under investigation. GnRHa trigger is likely to become the future gold standard trigger concept in IVF.

Ovulation: Dual Trigger

Glossary

Assisted reproduction technology (ART) Is the technology used to achieve pregnancy in procedures such as fertility medication, in vitro fertilization and surrogacy. It is reproductive technology used primarily for infertility treatments, and is also known as fertility treatment. It mainly belongs to the field of reproductive endocrinology and infertility, and may also include intracytoplasmic sperm injection (ICSI) and cryopreservation. Some forms of ART are also used with regard to fertile couples for genetic reasons (preimplantation genetic diagnosis).

Follicle-stimulating hormone (FSH) Is a gonadotropin, a glycoprotein polypeptide hormone. FSH is synthesized and secreted by the gonadotropic cells of the anterior pituitary gland, and regulates the development, growth, pubertal maturation, and reproductive processes of the body. FSH and luteinizing hormone (LH) work together in the reproductive system.

Luteinizing hormone (LH) Also known as lutropin and sometimes lutrophin is a hormone produced by gonadotropic cells in the anterior pituitary gland. In females, an acute rise of LH ("LH surge") triggers ovulation and development of the corpus luteum.

Introduction

One of the objectives of an in vitro fertilization cycle (IVF) is to retrieve an adequate number of mature oocytes to fertilize, thereby to optimize the chances of gestation. To trigger the release of mature oocytes, at the end of the controlled ovarian hyperstimulation (COH) protocol, human chorionic gonadotropin (hCG) is often administered as a surrogate LH surge. hCG exhibits structural and biological similarities to LH, and they bind and activate the same receptor, the LH/hCG receptor (Kessler et al., 1979). One major difference between them is that the half-life of natural LH is about 60 min, but that of hCG exceeds 24 h (Yen et al., 1968; Damewood et al., 1989).

The use of hCG has some adverse consequences. Indeed, hCG appears to negatively affect both endometrial receptivity (Simon et al., 1995; Forman et al., 1998; Simon et al., 1998) and embryo quality (Valbuena et al., 2001; Tavaniotou et al., 2002). Further, the sustained luteotrophic effect of hCG is associated with increased chances of ovarian hyperstimulation syndrome (OHSS), which is an iatrogenic complication of assisted reproductive technology (ART) (Practice Committee of the American Society for Reproductive Medicine, 2003). These negative outcomes have prompted explorations of alternative approaches to induce an LH surge.

One such alternative is the use of gonadotropin-releasing hormone (aGnRH) agonists. aGnRH administration triggers the release of endogenous luteinizing hormone (LH) (Gonen et al., 1990; Olivennes et al., 1996; Olivennes, 2001; Tay, 2002). Its use is applicable only in IVF cycles using COH treatment regimens in which the cycle has been down-regulated by a GnRH antagonist. Subsequent oocyte maturation triggering with GnRH agonists reduces the risk of OHSS due to quick and irreversible luteolysis (Kol, 2004). However, evidence suggests that using aGnRH as a final oocyte maturation trigger in fresh autologous cycles is associated with a significant reduction in the clinical pregnancy rate (Griesinger et al., 2006). This prompts questions about the value of substituting aGnRH for hCG.

To overcome this effect on pregnancy rates, a more recent development is the use of "dual trigger." The dual trigger approach combines a bolus of aGnRH simultaneous with hCG administration. This strategy captures the benefits of GnRH agonists and hCG in the induction of ovulation, but strives to improving pregnancy rates in patients without adding a risk of OHSS.

Luteinizing Hormone (LH) and Follicle-Stimulating Hormone (FSH) in Natural Cycles

The ovarian cycle requires a coordinated interaction along the hypothalamic-pituitary-ovarian axis. The pulsatile secretion of GnRH by the hypothalamus activates the synthesis of gonadotrophins (FSH and LH) by the anterior hypophysis. FSH and LH act directly on the ovary, promoting follicular maturation and the production and subsequent secretion of steroid hormones that act at the endometrial level (Sociedad Española de Fertilidad, 2017).

LH secretion induces the ovulatory cascade (ovulation occurs between 34 and 36 h after the start of the LH peak). It also re-starts the arrested meiotic development of the oocytes; promotes luteinization of granulosa cells in the dominant follicle, resulting in the production of progesterone; and provokes cumulus expansion and synthesis of prostaglandins essential for follicle rupture. (Fritz and Speroff, 2011) On the other hand, FSH induces nuclear maturation (resumption of meiosis) (Zelinski-Wooten et al., 1995), activity of LH receptors in granulosa cells (Zeleznik et al., 1974; Richards et al., 1976), and cumulus cell expansion

(Strickland and Beers, 1976; Eppig, 1979). FSH also has an important role in maintaining communication between cumulus cells and oocytes (Atef et al., 2005).

hCG and Ovarian Hyperstimulation Syndrome

OHSS is a medical condition affecting the ovaries of some women following an ART cycle. Most cases are mild, but rarely the condition is severe and can lead to serious illness or death (Shmorgun et al., 2011). The fundamental etiological factor in OHSS onset is hCG exposure, which increases vascular permeability by stimulating the production of vascular endothelial growth factor (VEGF) (Gómez et al., 2002). hCG exposure can result from endogenous (trophectoderm implantation) production or exogenous administration (pharmacological induction of ovulation).

We can distinguish two types of OHSS: early OHSS occurs 2–5 days after administration (exogenous) of hCG for the induction of ovulation; late OHSS is produced by embryonic implantation and secondary to the secretion (endogenous) of hCG by the trophoblast. Late OHSS is more severe and can last up to eight weeks. Importantly, this iatrogenic complication can be avoided by triggering ovulation with aGnRH instead of hCG in patients at high risk for OHSS.

Ovulation Induction With aGnRH

aGnRH is a viable alternative to hCG for triggering endogenous LH release (Gonen et al., 1990; Olivennes et al., 1996; Olivennes, 2001; Tay, 2002). However, it must be used only in those IVF cycles with COH treatment regimens including down-regulation by a GnRH antagonist. A single injection of aGnRH results in an acute release of LH and FSH, an effect called “flare up”. Serum LH and FSH levels rise after 4 and 12 h, respectively, and are elevated for 24–36 h. The amplitudes of the surges are similar to those observed in a natural cycle. However, in contrast to the natural cycle, the LH surge consists of two phases: a short ascending limb (>4 h) and a long descending limb (>20 h) (Youssef et al., 2014).

Triggering oocyte maturation with GnRH agonists reduces the risk of OHSS due to fast and irreversible luteolysis (Kol, 2004). This approach may result in better oocyte and embryo quality due to a more physiological LH and FSH surge (Humaidan et al., 2005). Importantly, though, evidence suggests that using aGnRH to provoke final oocyte maturation in fresh autologous cycles may lead to a significant reduction in the clinical pregnancy rate (Griesinger et al., 2006), a lower live birth rate, a lower ongoing pregnancy rate (pregnancy beyond 12 weeks), and a higher rate of early miscarriage (<12 weeks) (Griesinger et al., 2006; Youssef et al., 2014). These outcomes suggest that alternative approaches are needed to overcome the problems with hCG administration (OHSS) while maintaining the clinical outcomes of ART (pregnancy and birth rates).

Dual trigger

The dual trigger approach combines a bolus of aGnRH is delivered at the time of hCG administration. This method combines the advantages of both hCG and aGnRH induction regimens:

- (1) It decreases the risk of OHSS by decreasing the dose of hCG;
- (2) It is a more physiological cycle since there is the addition of an FSH peak induced by GnRH agonist, generating a larger number of mature oocytes (Griffin et al., 2014); hCG alone induces only an LH peak (Decleer et al., 2014);
- (3) It improves endometrial receptivity for releasing endometrial GnRH receptors (Schachter et al., 2008).
- (4) It extends the ovulation time after use of the induction caused by hCG, also improving oocyte maturation (Zilberberg et al., 2015); and
- (5) There is better luteal phase recruitment when there is a proven combined use of hCG with GnRH agonist (Shapiro et al., 2011).

This strategy has been studied in different patient groups with GnRH antagonist IVF protocols. In high responders, Shapiro et al. (2011) and Griffin et al. (2014) showed an improvement in pregnancy and implantation rate with respect to the single trigger with aGnRH; however, neither of those two studies resulted in complete elimination of the risk of OHSS. Among normo responders, Lin et al. (2013) and Kim et al. (2014) showed an improvement in pregnancy and implantation rates following dual trigger with respect to the single trigger with hCG; on the other hand, Decleer et al. (2014) reported no significant differences between dual trigger and single trigger in terms of pregnancy and implantation rates. Finally, in patients with previous failed cycles, Schachter et al. (2008) showed an increase in pregnancy and implantation rates following dual trigger. Griffin et al. (2014) found that, among patients with large numbers of immature oocytes, there was an increase in the % of oocytes and mature oocytes retrieved following dual trigger.

Conclusions

Dual trigger for final oocyte maturation is a good alternative to hCG alone after ovarian stimulation with recombinant FSH and LH and suppression of premature LH surge with GnRH antagonist. This approach may have particular benefit for poor

responder patients or patients with immature oocytes. However, the prognosis of these patients remains unfavorable, possibly due to a basic ovarian problem difficult to resolve. The use of dual trigger in high and normal responder patients, since the majority of studies show a benefit in terms of improving pregnancy and implantation rates, does not completely eliminate the risk of OHSS. Thus, special care must be taken with the indication of dual trigger among these patients. More prospective randomized studies will help better define the use of this approach. In particular, studies combining these IVF regimens with preimplantation genetic diagnosis of the embryos will help identify the impact of dual trigger on embryo quality.

Glossary

Asherman syndrome (Syn amenorrhea traumatica) condition named after Joseph G Asherman, first described in 1948, characterized by adhesion and fibrosis of the endometrium, following trauma. It results into absence of menstruation and infertility. It is frequently associated with curettage of the endometrium.

Angiogenesis Formation and growth of new blood vessels. This process is vital in the growth and maintenance of an organism, as well as in wound repair.

Biopsy Medical test involving sampling of cells or tissue for examination to determine the presence or extend of a disease.

Cochrane review The Cochrane Database of Systematic Reviews (CDSR) is the leading resource for systematic reviews in health care.

Cytokines A broad and loose category of small proteins (~5–20 kDa) that are important in cell signaling. Their release has an effect on the behavior of cells around them. They are different from hormones.

Decidua The part of the endometrium that in higher placental mammals undergoes special modifications in preparation for and during pregnancy and is cast off at parturition.

Endometrial stroma Part of the endometrial tissue that has a supportive and connective function. It contains mainly blood vessels, specialized supportive cells and immune cells.

Endometrium The endometrium is the inner lining of the uterus. It is a mucosal lining that changes in thickness and composition during the menstrual cycle. It is composed of two layers: the basal layer which is the deepest layer and will not change much during the cycle and the functional layer that will undergo changes in order to allow the implantation of an embryo. The functional layer is responsive to hormones. In the first part of the menstrual cycle, estrogen causes growth of the endometrium. In the second part of the cycle, progesterone induces differentiation to enable the embryo implantation.

Epithelium One of the basic types of animal and human cells, lining the surface of cavities and organs.

Hysteroscopy Procedure inspecting the uterine cavity by endoscopy through the uterine cervix. The procedure can be used for diagnostic and therapeutic intentions.

Implantation The process of attachment and invasion of an embryo in placental animals.

In-vitro fertilization (IVF) Assisted reproductive technique where one or more human eggs (oocytes) are combined with sperm outside the body to allow fertilization. The obtained embryo is transferred to the uterus to obtain a pregnancy.

Oocyte donation Procedure by which one women donates her eggs to another women in order to allow her to conceive.

Peritoneum The [serous membrane](#) that forms the lining of the [abdominal cavity](#).

Pipelle biopsy The Pipelle de Cornier is a flexible polypropylene device enabling a blind sample of the endometrium. It is largely used in the diagnosis of several endometrial diseases.

Recurrent implantation failure (RIF) The failure to achieve a pregnancy after 3 completed fresh embryo transfer cycles with good morphological embryo quality into a normal uterus.

Definition

Endometrial scratching is defined as ‘intentional damage to the endometrium, performed with the objective to improve reproductive outcome of women or couples desiring pregnancy’.

Introduction

Having a child is an important issue for many couples. Up to 10% of couples will not achieve pregnancy spontaneously. Many of them will seek help from fertility treatments in order to conceive. Success rate of infertility treatments is limited, as, at best, in-vitro fertilization (IVF) will lead to a live birth rate of only 30% per cycle ([Kupka et al., 2014](#)).

Each cycle, in the proliferative phase, the endometrium is build up under the influence of the ovarian hormone estrogen, until ovulation occurs. After ovulation, the ovarian corpus luteum will produce progesterone. This hormone initiates the secretory phase of the endometrium. In the presence of an embryo, implantation will occur during a short time span. This time span, also called implantation window, is the result of a precisely orchestrated modulation lasts for approximately 4 days. During this period, the endometrium is called ‘receptive’ to allow an embryo to implant.

Failure of IVF treatments is due to several factors, from which a lack of endometrial receptivity is thought to account for up to two-thirds of unsuccessful pregnancy outcomes. Further gain in pregnancy rates must, therefore be targeted from an improved endometrial environment.

One technique to enhance implantation is to perform an intentional injury to the endometrium prior to IVF treatment, also referred to as 'endometrial scratching',

According to a recent survey, up to 83% of clinicians already recommend some form of scratching procedure as part of routine clinical treatment for their patients (Lensen et al., 2016).

Endometrial Scratching: The Theory behind Biological Mechanism of Action

Different theories by which endometrial injury may interact with implantation have been proposed. Evidence is mainly derived from experiments in animal models and from laboratory in-vitro tissue culture of human endometrial tissue.

Experiments in Animal Models

The idea that local injury to the endometrium may be beneficial for pregnancy is an old concept. In guinea pigs, mice and rats, different types of injury have been studied. Already in 1907 (Loeb, 1907) reported that scratching the uterus of the guinea pig provoked a reaction of the endometrium that resulted in an improved receptivity. The same observations were made in mice and rats, if scratching was replaced by the injection of oil into the uterine horns. The presence of a thread in the uterine lumen, inserted for one day, provoked the same effect.

These early studies in rodents and guinea pigs all demonstrated a similar effect of the endometrium resulting from local injury. The stromal cells of the endometrium underwent a rapid decidual reaction, which was responsible for an increased implantation after embryo replacement.

More recently, effect of injury on another type of endometrial cells was observed. Experimental endometrial injury caused by injection of lipopolysaccharide into the peritoneum (Hyodo et al., 2011) resulted in a rapid increase in side population (SP) cells, which are equivalent to endometrial adult stem/progenitor cells. Stem cells are responsible the unique regenerative capacity of endometrial tissue. The effects of the injury were hormone-dependent, as the number of SP cells increased in the presence of estrogen and was blocked by progesterone.

In other experiments, it was demonstrated that injury has a long-term effect on the endometrium, persisting until the following menstrual cycle. Standardized local injury in mice uteri improved embryo implantation. The mice uteri were examined in the cycle that followed the injury. They showed a better morphology and also increased expression of specific implantation-related cytokines. From these observations in a mouse model, it was concluded that mechanical injury in a given cycle results into better endometrial receptivity and improves embryo implantation in following cycles (Zhang et al., 2015).

Experiments in Endometrial Tissue Cultures

In an attempt to understand the mechanism of endometrial injury, human endometrial tissue cultures can be prepared and observed in a laboratory. These so-called in-vitro cultures can be conditioned in a way that mimics an injury-like environment. Tumor necrosis factor (TNF-alpha) is a cytokine capable to initiate an inflammatory stimulus, similar to injury. When applied in in-vitro cultured human endometrial cells, recovered on a non-receptive cycle day (day12) and a receptive cycle day (day 21) of the menstrual cycle, TNF-alpha treated stromal cells were able to express cytokines that attract monocytes, a particular type of white blood cells. Subsequently, TNF-alpha induced further differentiation of these monocytes into dendritic cells, which are another type of immune cells. In turn, these dendritic cells stimulated the endometrial epithelial cells to produce several factors involved in embryo implantation: osteopontin and its receptors along with the up-regulation of genes involved in embryo adhesion (Fig. 1). At the same time, TNF-alpha caused a down-regulation of molecules that are present in the non-receptive endometrium. The hypothesis was made of a 'tissue memory' effect that may explain a favorable effect of the recruited monocytes in further treatment cycles.

In other experiments, injury increased the population of natural killer (NK) cells. NK cells are immune cells involved in the implantation process. They are crucial in stromal cell differentiation, immune modulation and angiogenesis during implantation. It has been shown that the number of NK-cells is decreased in IVF cycles. Thus, an injury stimulating an increase of these cells could be considered beneficial. However, the injury seemed to have no effect on angiogenesis, warning against an over-simplistic view on the potential clinical benefit.

Although tempting, results from experiments in animal models and cell cultures must be considered with caution before they can be extrapolated to the in-vivo human condition or applied in patient care.

It is not yet proven that experimental injury enhances the naturally initiated shift from a non-receptive to a receptive endometrial condition in humans. Also the 'tissue memory' hypothesis deserves further documentation.

Hypothesis of Action in Human

There are different hypothesis attempting to explain the clinical effects of endometrial scratching (Siristatidis et al., 2014). For each theory, pro's and contra's can be argued.

Fig. 1 Hypothesis of biological action of endometrial scratching in IVF patients: Scratching is thought to counter the gene shift induced by the IVF therapy. In the endometrial stroma (insert), scratching induces decidual (DEC) transformation of the stromal cells (SC). From the blood vessels (BV) there is an outflow of monocytes (M), transformed into dendritic cells (DC). Scratching also attracts natural killer cells (NK). In the endometrial epithelium (insert), the latter process will release cytokines involved in implantation (LIF, Oncost M) and decrease adhesion molecules (MUC-6) that interfere with embryo adhesion.

Injury Induces Local Decidual Changes in the Endometrium

A focal decidual reaction of the endometrial tissue in women has been described following the mechanical irritation caused by an embryo transfer catheter (Dallenbach-Hellweg et al., 1984). Various histological reaction patterns according to the timing of the catheter insertion were observed. If the catheter was inserted during the proliferative phase, no or minimal response was visible, whereas insertion in the secretory phase induced a focal decidual change of the endometrial stroma in the majority of the patients. Patients taking oral contraceptives showed no response to the catheter stimulus.

Pro: the human endometrium seems to be capable of focal, cycle phase-dependent and hormonal therapy-related response to mechanical stimulation. Contra: it is not certain that a local decidual change increases endometrial receptivity. Indeed, in a normal conceptive cycle, decida is not yet initiated during the limited time span by which the endometrium will accept an embryo that is about to implant. Decidual changes of the endometrium will only appear at a later stage of the luteal phase and will be a prerequisite for maintenance of an already established implantation. Therefore, artificially induced decidualization by injury may occur at a too premature time point.

Implantation According to the Wound-Healing Theory

It has been proposed that human embryo implantation is an inflammatory process bearing similarities to trauma, when white blood cells migrate from the blood vessels into the surrounding tissue (Gnainsky et al., 2015). Injury would thus induce secretion of wound-healing cytokines, which are similar to those beneficial for implantation.

Pro: theories claiming special attraction for the embryo to scar tissue of a cesarean section have been proposed.

Pro: wound-healing cytokines are associated with an inflow of certain immune cells, especially macrophages and dendritic cells. In women treated by IVF with a history of implantation failure, injury to the endometrium resulted into a statistically significant higher number of both types of immune cells. The immune cells enhance the production of cytokines in the endometrium. There is a positive correlation the levels of certain cytokines (namely, macrophage inflammatory protein 1B and TNF-alpha) and subsequent pregnancy rates in the following IVF cycle.

Contra: implantation of an embryo within scar tissue is a rare event and the majority of implantation sites following a cesarean section are located remotely from the scar. Moreover, the deep placental invasion into the myometrium (and beyond the scar tissue) is most likely to result from a failure rather than from an increased endometrial decidual response, thus also invalidating the previous hypothesis.

Theory of Injury-Induced Gene Expression Shift

It has been demonstrated that IVF therapies are responsible for an abnormal gene expression leading to a premature secretory change of the endometrium, which may cause the embryo to miss the implantation window.

This hypothesis assumes that injury restores a better embryo-endometrial synchrony and corrects the changes caused by the IVF therapy.

Pro: In a natural menstrual cycle, endometrial injury on cycle days 11–13 and 21–24 modulates several genes on day 20–21 of the next spontaneous cycle.

Contra: this backward development theory is likely to be over-simplistic, since endometrial advancement in IVF has only been described in the very first days of the secretory phase, but not at the time of presumed implantation. Furthermore, it also needs to be emphasized that no specific endometrial gene signature has yet been defined in IVF cycles with successful pregnancy outcome.

Taken together, there is substantial documentation on a short-term inflammatory response following intentional endometrial trauma, which recalls elements from the natural embryo implantation process. However, the evidence pointing to its exact implication in enhanced endometrial receptivity is fragmentary. A lasting effect of scratching in subsequent cycles needs yet to be clarified, all benefit remaining largely hypothetical.

Endometrial Scratching in Patients. What, Who, When and Why?

Evidence from Clinical Trials

Barash *et al.* (2003) was the first to postulate a beneficial effect of an endometrial biopsy taken before initiation of the IVF treatment cycle. He demonstrated a doubling in implantation, clinical pregnancy and live birth rates (2). More recently, over 1000 publications addressed the topic of endometrial scratching. Evidence derived from systematic reviews and meta-analysis (Nastri *et al.*, 2015) modestly favored a benefit of performing a local endometrial injury. The conclusions from these reviews indicate the greatest benefit in women with unexplained recurrent implantation failure (RIF). According to these conclusions, scratching should preferentially be performed in the cycle preceding the IVF treatment cycle. The technique of endometrial scratching is presented as an easy to perform and low-cost procedure, potentially increasing the IVF outcome.

There is severe criticism to these studies. Detractors point to methodological weaknesses of the presented data and a general lack of basic scientific evidence to prove a definite efficiency of endometrial scratching in improving the pregnancy outcome (Santamaria *et al.*, 2016).

In the general IVF population (i.e. patients without recurrent implantation failure) or in other procedures of assisted reproduction such as intra-uterine insemination or oocyte donation, scratching did not improve pregnancy outcome. In these patient groups, there is no indication to perform a scratching procedure. In view of these flaws, it is not possible to ascertain a beneficial effect of scratching and it is thus not recommended to implement the procedure in clinical practice unless more robust evidence becomes available. Besides defining which patient population may benefit from the scratching procedure, several other points such as tools, methods and timing for scratching also need to be standardized (Bourgain *et al.*, 2017).

Curiously, despite this lack of evidence, the procedure is already proposed in many fertility clinics for women with recurrent implantation failure. Several ongoing clinical trials are now trying to address the gaps in the utility of the scratching procedure (Lensen *et al.*, 2016; Lensen *et al.*, 2016). These are conducted in patients receiving fertility treatments or trying to conceive naturally. Further evidence of benefit must be awaited from those studies before the procedure can be implemented in routine practice.

Tools and Methods for Endometrial Scratching

There is no dedicated device to perform an endometrial scratching. Most commonly, an endometrial Pipelle biopsy device by Cornier is used for this purpose. A sample of the superficial layers of the endometrium is retrieved by suction and rotation. There is a need for standardization of the procedure, when applied to induce intentional injury. Until now, there is no consensus on the number of biopsies (single procedure or multiple procedures over different days). Neither is the technical method of intervention using the Pipelle biopsy standardized (360 degrees rotation with 4 up-and-down movements or scratching the whole endometrial cavity for a number of seconds). Alternative methods of injury include hysteroscopic irrigation with saline, endometrial damage provoked by a neonatal feeding tube, use of an endometrial biopsy catheter, a Novak curette or a grasping forceps with teeth. Although not included in the Cochrane definition of endometrial scratching, hysteroscopy can also be considered to cause some extent of endometrial injury.

The indication for endometrial injury is also poorly defined, as the procedure has been applied not only in patients with a normal cavity, but also in sub-fertile patients with the intention to treat intra-uterine anomalies such as polyps and fibroids. Even in the latter group, the benefit of systematic hysteroscopic surgical approach remains controversial.

Clearly, one cannot expect to draw consistent information from such highly divergent 'scratching' techniques in variable clinical indications.

It must also be mentioned that injury methods in clinical studies differ considerably from those applied in the experimental settings from which the different hypothesis of the biological actions of scratching were retrieved.

Another methodological gap in the current literature is the lack of a well-defined 'no injury' control population. Controls vary from no intervention to sham procedures, such as cervical biopsy or even hysteroscopy without biopsy. Especially the latter procedure may cause unintentional disturbance to the endometrial tissue.

There is an urgent need for guidelines to standardize the 'scratching' technique and to define the control population where no injury is performed.

When Is the Best Timing for Endometrial Scratching?

There appears to be no standardized clinical procedure reported for the best moment where endometrial scratching should be performed.

Among the different reports, there is a large variability concerning the timing of endometrial injury. Most studies advocate the intervention performed in the cycle preceding IVF, either in the proliferative or luteal phase or even both (Fig. 2). Less commonly,

Fig. 2 The endometrial scratching is preferentially performed with a Pipelle biopsy device in the menstrual cycle that precedes the IVF treatment.

the injury is performed in the proliferative phase of the IVF cycle. A biopsy in the IVF cycle, closer to the implantation day is not recommended, being associated with a lower pregnancy outcome. Consensus guidelines upon the best timing to perform endometrial scratching still need to be developed.

Complications Due to Endometrial Scratching

Multiple pregnancy and miscarriage rates following endometrial scratching are very poorly documented and no conclusion can therefore be drawn from current literature.

Pain and bleeding are underreported and have only been assessed systematically in one study (Nastri et al., 2013), whereas elsewhere, only spontaneous pain complaint was reported. It is presumed that endometrial scratching is associated with a subjective increase in pain and a risk of bleeding. Theoretically, endometrial scratching in the luteal phase could be harmful to a spontaneous pregnancy, occurring at that moment. Therefore, couples are asked to refrain from intercourse in the cycle where scratching is performed. There is no documentation on the potential risk of Asherman syndrome. More systematic studies are warranted from a standardized 'scratching' procedure to address these adverse events.

Post-injury infection has not been reported. There is insufficient evidence to recommend the use of prophylactic antibiotics.

Overall, the procedure seems to be quite easy to perform in an out patient setting, to carry little risk and to be fairly well tolerated. Nevertheless it must be kept in mind not to propose a painful intervention at a supplementary cost to women without established added benefit.

Conclusions

Endometrial 'scratching' is an easy to perform and therefore tempting procedure to increase pregnancy outcome as part of a fertility treatment. To date, fragmentary and insufficient scientific evidence is available to prove a biological mechanism for a beneficial effect of local injury on endometrial receptivity. Curiously enough, despite this lack of proof, scratching is already proposed as a standard of care in numerous reproductive medicine units.

Clinical evidence must await further data from well-designed randomized trials to define the target patient population to whom the procedure could be of benefit. Standardized guidelines for a specific instrument, method and timing of scratching need to be established before implementation in routine practice.

Implantation: Physiology

In order to produce a viable pregnancy, the competence of both the embryo and the endometrium must be ensured. In murine models, the luminal epithelium remains non-receptive to implantation for the first 3 days following the union of spermatozoa with the oocyte, despite adequate preparation of the endometrium with ovarian-derived estrogen and progesterone. At the blastocyst stage, appositional contact with the luminal epithelium can be seen. It is at this time that an additional small surge of ovarian estradiol is required to induce the synthesis of cytokines involved with implantation, for example, leukemia inhibitory factor (LIF), a pro-inflammatory cytokine belonging to the interleukin-6 (IL-6) family. LIF is a glycoprotein which activates the Janus kinase—signal transducer and activator of transcription (JAK-STAT) pathway in the luminal epithelium. As a result, many transcription factors are produced, effecting a cascade of changes. Ultimately, due to LIF and other cytokines, the uterine luminal epithelium is transformed from a non-receptive to a receptive state ([Rosario and Stewart, 2016](#)).

The receptive endometrium often exhibits bulbous protrusions on the surface of the epithelial lumen and stromal cells that are primed to decidualize with application of the appropriate stimuli. Additionally, the receptive endometrium displays reorganization of the stromal extracellular matrix components that allows for decidualization and secretes stage-specific glycoproteins through the lumen. Once decidualization occurs, the basement membrane components appear within the matrix ([Yoshinaga, 1988](#)).

Once a receptive endometrium is established, it must then interact with the embryo. Adherence of the embryo to the endometrium is regulated by a family of cell adhesion molecules called integrins (ITG) ([Mangale and Reddy, 2007](#)). Specific integrins present on the luminal surface of the endometrium transduce cellular signals between uterine epithelial cells and trophoblastic cells. Specifically, α 5 β 1 integrin and integrin β 8 (ITGB8) are implicated in blastocyst attachment and can regulate vascular development via activation of vascular endothelial growth factor or transforming growth factor β 1 (TGFB1) ([Apparao et al., 2001](#); [Kumar et al., 2015](#)). Disruptions in the aforementioned complex sequence of events can lead to failure of implantation.

The impact of the immune system at the level of the endometrium has been identified to potentially play a role in determining the success or failure of implantation, even in the absence of infection. For example, imbalances in cytokines produced by T-lymphocyte helper cells-1 and 2 (T_H1 and T_H2 , respectively) can contribute to implantation failure, as pregnancy is considered a T_H2 -dominant state. Whether an imbalance occurs as a result of a failed pregnancy or is the cause of a failed gestation is not well-delineated at this time ([Fransia and Scott, 2017](#)). The role of natural killer (NK) cells on recurrent implantation failure has also been extensively studied, however, a meta-analysis of 12 studies did not find an association between pregnancy outcomes and peripheral NK cell activity or quantity or uterine NK density ([Tang et al., 2011](#)).

While the evidence for immunologic interference or assistance in reproductive success is conflicting, other endometrial factors have also been postulated to influence implantation. For example, an abnormal structure of the endometrial cavity, such as uterine hypoplasia, can result in impaired reproductive outcomes ([Berger and Goldstein, 1980](#)). The presence of infection, such as chronic endometritis, can also impact the receptivity of the endometrium. In such cases, an abnormal pattern of lymphocyte subsets are identified within the endometrium, leading to an abnormal endometrial microenvironment. This has been shown by some investigators to decrease reproductive potential ([Matteo et al., 2009](#); [Cicinelli et al., 2014](#)).

It should be noted that the physiology of embryonic and endometrial development can be altered. This is not due to a reproducible pathology in the processes described above. In these cases, it is likely that dyssynchrony exists between the endometrium and the embryo, precluding pregnancy in an otherwise normal endometrium and presumably normal embryo. For implantation to occur, the embryo and endometrium must not only be normal, but the window of embryonic implantation and window of endometrial receptivity must align. Synchrony implies that the endometrium is receptive at the time that the embryo is prepared to implant.

Assessment of the Embryo

With regard to implantation failure, investigators have traditionally evaluated the embryo and the endometrium in isolation. Since the time of the first embryo transfers, significant advances have been made in both laboratories and embryo culture systems. At present, most laboratories culture embryos to the cleavage stage, the blastocyst stage, or commonly, both. A 2016 Cochrane Database Systematic review of 27 randomized controlled trials (RCTs) of 4,031 couples compared the success of cleavage stage versus blastocyst transfers. Primary outcomes included live birth rates and cumulative clinical pregnancy rates. Secondary outcomes included multiple pregnancy, miscarriage, embryo cryopreservation and inability to produce an embryo for transfer. The authors found higher clinical pregnancy and live birth rates following fresh transfer in the blastocyst group as compared with cleavage stage (day 2 or 3) group (odds ratio (OR) 1.30, 95% confidence interval (CI) 1.14 to 1.47; 27 RCTs, 4031 couples; OR 1.48, 95% CI 1.20 to 1.82; 13 RCTs, 1630 couples, respectively). There was no difference seen between groups with regard to miscarriage (OR 1.15, 95% CI 0.88 to 1.50; 18 RCTs, 2917 couples) or multiple pregnancy (OR 1.05, 95% CI 0.83 to 1.33; 19 RCTs, 3019 couples). However, couples were two times more likely to have no embryos available for transfer in the blastocyst group (OR 2.50, 95% CI 1.76 to 3.55; 17 RCTs, 2577 couples). The quality of evidence was assessed using Grading of Recommendations, Assessment, Development and Evaluations (GRADE) methods and found to be low for most of the main comparisons in each study, with the major limitation being risk of bias. In most of the included studies, this risk was attributed to failure to describe acceptable methods of randomization. The authors of the review concluded an overall benefit of blastocyst transfer over cleavage stage transfer, although the impact on cumulative pregnancy and live birth rates could not be ensured given the inherent limitations of the 27 RCTs cited ([Glujovsky et al., 2016](#)).

A recent study from De Vos and colleagues also showed significantly higher live birth rates per started cycle after transfer of a blastocyst compared with a cleavage-stage embryo ([De Vos et al., 2016](#)). Additional findings included a reduced number of embryo transfer necessary until the first live birth when using blastocyst-stage embryos. Therefore, it is surmised that embryos with the capability to develop to the blastocyst stage in vitro demonstrate higher pregnancy potential. Additionally, if preimplantation genetic screening is to be used to select a euploid embryo for transfer, blastocysts tolerate this procedure without detriment, while cleavage stage embryos do not ([Scott et al., 1993](#)). In a randomized control trial using a paired design, the biopsy procedure itself was demonstrated to have no adverse impact on the pregnancy potential of the embryos.

An important addition to the consideration of extended embryo culture is the assessment of embryonic development for synchrony. This was not evaluated or discussed in the previously mentioned Cochrane review. The duration of culture required to reach the blastocyst stage is not uniform amongst embryos, even between those obtained within the same cycle and from the same patient. The time to develop to the blastocyst stage takes between 5 and 7 days. The only way to monitor embryos for blastulation is through assessment during extended culture. If blastulation occurs late, the endometrium may be no longer receptive to the embryo after a physiologically early progesterone stimulus, as we will see. Such dyssynchrony can be circumvented by the cryopreservation of embryos obtained from the controlled ovarian hyperstimulation cycle. A programed transfer cycle with a known progesterone start and transfer of a cryopreserved embryo (which was an expanded blastocyst at the time of vitrification) can ensure synchrony between the endometrium and the embryo chosen for transfer ([Franasiak et al., 2016](#)).

Assessment of the Endometrium

Our assessments of the endometrium continue to evolve. Endometrial biopsies were once commonly performed in efforts to diagnose a luteal phase defect, in which it was believed that low mid-luteal progesterone levels were responsible for conception and pregnancy failure. A later investigation by Scott *et al* revealed that endometrial dating by histologic criteria had poor intra-observer reliability, potentially explaining the conflicting reports published on the topic ([Scott et al., 1993](#); [Murray et al., 2004](#)). The Reproductive Medicine Network later confirmed these findings, reporting the greatest observer variability in histologic dating of the endometrium occurred when assessing the window of implantation in infertile women ([Myers et al., 2004](#)).

Furthermore, luteal serum progesterone levels have historically been measured to identify a luteal phase defect as a method for describing issues with endometrial physiology which can cause implantation issues. However, it has been demonstrated that serum progesterone levels vary widely throughout the luteal phase. Filicori *et al* demonstrated that luteal progesterone is characterized by a pulsatile pattern, as its production is dependent on luteinizing hormone (LH) ([Filicori et al., 1984](#)). Therefore, in a natural cycle, the serum progesterone level confers little predictive value.

Next, the advent of routine use of transvaginal ultrasound into clinical practice has allowed visualization of the endometrium throughout the menstrual cycle. Studies correlating ultrasound findings to endometrial histology have enhanced our understanding of the sonographic features of endometrial abnormalities. Many aberrations in endometrial development can easily be visualized on ultrasound, including the presence of a thin endometrium in the late follicular phase, a hyperechoic endometrium in the late follicular phase ([Fanchin et al., 2000](#)), or a hyper-contractile endometrium identified in the luteal phase. However, a 2014 systematic review and meta-analysis reported that endometrial thickness has limited ability to predict chances of conceiving in IVF cycles. A very thin endometrial lining (measuring <7 mm) appeared to be related to a lower chance of pregnancy, but such a finding occurs infrequently in isolation and therefore, adds limited prognostic value ([Kasius et al., 2014](#)).

Most recently, extensive work in transcriptomic profiling has demonstrated the possibility of classifying human endometrial receptivity at a molecular level. Ruiz-Alonso and colleagues published their success with the endometrial receptivity array (ERA),

Fig. 1 The timing of the onset of the progesterone stimulus is critical to synchrony. In natural conception, secretory transformation begins and the window of endometrial receptivity opens several days later. This is synchronous with the timing of blastocyst development (A). In some patients, the window of implantation is pathologic; i.e., trending towards accelerated or retarded development (B). In ART cycles, endometrial-embryo dyssynchrony is usually not due to endometrial pathology, but rather, secondary to aberrant timing of the progesterone stimulus (C).

a molecular diagnostic tool containing 238 genes expressed differentially during the menstrual cycle with the capability to identify the endometrial receptivity of a sample. Unlike endometrial biopsy, this test has been shown to show intra-patient reproducibility and has shown success in defining a personalized window of implantation (Ruiz-Alonso et al., 2013).

Such assessments of the endometrium evaluate pathology. For example, the endometrial receptivity array can identify patients whose window of implantation is pathologic; that is, trending towards accelerated or retarded development (Fig. 1A). However, in ART cycles, endometrial-embryo dyssynchrony is usually not due to endometrial pathology, but rather, secondary to aberrant timing of the progesterone stimulus. The timing of the onset of the progesterone stimulus is critical to synchrony. Once progesterone reaches a threshold value after ovulation, secretory transformation begins and the window of endometrial receptivity opens several days later (Fig. 1B).

Synchrony and Dyssynchrony Between the Embryo and the Endometrium

In a natural cycle, the follicle facilitates coordination between the endometrium and the embryo. At approximately the same time that the spermatozoa meet the oocyte, a secretory transformation of the endometrium occurs secondary to a post-ovulation elevation in progesterone (Fig. 1C). This rise in progesterone serves as the stimulus that initiates the opening of the endometrium's window of receptivity. Development will proceed synchronously if the embryo and endometrium are both normal. In an assisted reproduction cycle, this coordination must be replicated.

The window of implantation can be divided into the possible window of implantation and the optimal window of implantation. Early studies posited that the window was 3–5 days in length. In a study by Navot et al, day-2 embryos were transferred between cycle days 16 through 24. Pregnancies were noted to result after transfers on days 16–20, with the majority resulting after transfer on cycle days 17–19 (Navot et al., 1991). Subsequent studies described a narrower window of implantation, with highest pregnancy rates occurring during a 2-day window (Prapas et al., 1998). In these subsequent studies, 2–6 days of progesterone was administered with subsequent transfer of day-2 embryos. Pregnancy rates were noted to decrease and abnormal placentation was found to increase at the later margin of the window (Prapas et al., 1998; Wilcox et al., 1999).

In a retrospective study, Bosch et al demonstrated that the endometrial window of implantation is influenced by the progesterone levels, as premature (late follicular) serum progesterone levels greater than or equal to 1.5ng/mL were associated with lower ongoing pregnancy rates (Bosch et al., 2010). Later meta-analysis data from Hamdine et al confirms reduced clinical outcomes with elevated late follicular progesterone rise (Hamdine et al., 2014). Santos-Ribiero et al subsequently described late follicular serum progesterone levels found to be either too high or too low were associated with reduced live birth rates after controlling for potential confounding factors (Santos-Ribiero et al., 2014).

Fig. 2 No difference in outcomes seen between day 5 euploid embryos and day 6 euploid embryos after cryopreservation with subsequent thaw and transfer in a programmed cycle (Forman et al., 2013). In this study, blastulation occurred more commonly after day 5 in women age 35 and older.

Detrimental clinical outcomes associated with a premature rise in progesterone seen in ART cycles are related to an earlier shift in secretory transformation of the endometrium. The progesterone rise occurs earlier and more quickly in IVF cycles as compared with natural cycles. As a result, the window of implantation is shifted approximately 16–24 h earlier in ART cycles. If progesterone rises even earlier in the late follicular stage, the window of implantation correspondingly shifts forward. Unlike patients with pathologic endometrium (i.e., displaying consistent retardation or acceleration of endometrial development), shifts of the window occurring in stimulated cycles are not reproducible from cycle to cycle. Once this characterization of the stimulus for the window of implantation in ART cycles has been identified, attention can be turned to the role of the embryo in synchrony.

Embryonic development has been studied with regard to those that can mature to the blastocyst stage in vitro. Prior to routine cryopreservation of embryos with transfer in a delayed programmed cycle, embryos that blastulated later were associated with reduced fitness (Shapiro et al., 2008; Barrenetxea et al., 2005). In fresh embryo transfer cycles, Barrenetxea et al demonstrated significantly higher implantation rates with embryos that reached blastocyst stage by day 5 post-fertilization as compared with those blastulating at day 6 (Barrenetxea et al., 2005). However, Shapiro et al showed that this effect disappeared when outcomes of thawed cryopreserved day 5 and 6 embryos were compared after transfer within programmed transfer cycles (Shapiro et al., 2008). These findings point to dyssynchrony between the embryo and the endometrium as a possible confounder that may explain the decreased competence of embryos that blastulate later. This concept was also demonstrated by Forman and colleagues, noting no difference in outcomes between day 5 euploid embryos and day 6 euploid embryos after cryopreservation with subsequent thaw and transfer in a programmed cycle (Forman et al., 2013). In this study, blastulation occurred more commonly after day 5 in women age 35 and older (Fig. 2). Later blastulating embryos coupled with an earlier shift in the window of endometrial receptivity seen in ART cycles results in a high likelihood that dyssynchrony will occur. As a result, dyssynchrony can potentially explain the diminution of clinical outcomes seen in many older patients. Alternatively, embryos from younger women tend to blastulate early, falling within the window of endometrial receptivity and resulting in improved clinical outcomes.

Management of Dyssynchrony

Prevention of dyssynchrony involves active management of both follicular stimulation and the timing of embryo blastulation in extended embryo culture. Late follicular serum progesterone may be monitored for an elevation above a threshold at-risk value, likely unique to each laboratory. It may be possible to prevent premature progesterone rise by carefully adjusting the ovarian stimulation. In an analysis of 10,280 first IVF cycles, Werner et al showed that LH or low-dose hCG can prevent premature late follicular rises in serum progesterone when added to the stimulation regimen. Specifically, the ratio of LH to follicle-stimulating hormone (FSH) of 0.3–0.6 was found to be optimal to prevent progesterone rise in both high and low responders (Werner et al., 2014). Preventing premature rises in serum progesterone is important when a patient is scheduled for a fresh embryo transfer, however, this is no longer pertinent with a frozen/thawed embryo transfer. Many studies have demonstrated the safety and even benefit of cryopreservation of embryos with replacement in a separate programmed cycle. The benefits include improved synchrony between the embryo and endometrium, decreased risk of ovarian hyperstimulation syndrome and improved pregnancy and fetal outcomes (Cobo et al., 2012). The latter benefits are ascribed to be the result of normalization of the hormonal milieu (Moreno and Franasiak, 2017).

In summary, embryo implantation is a complex process. The physiology of uterine receptivity is different in natural versus IVF cycles and should be treated as such. We know that synchrony between the embryo and the window of endometrial receptivity is essential, and therefore, both components must be scrutinized and actively managed in order to achieve optimal pregnancy outcomes. An improvement in clinical outcomes has been seen with transfer of blastocysts as opposed to cleavage-stage embryos. Given the available evidence, improved outcomes seen after the transfer of blastocysts are likely secondary to improved synchrony between the endometrium and the embryo, which can only be attained with extended embryo culture. Furthermore, the endometrium can be programmed toward receptivity to the blastocyst if embryo cryopreservation with subsequent thaw and careful timing of transfer is employed.

SPECIAL MEDICAL CONDITIONS

ART in Endometriosis

Graciela Kohls and Juan A Garcia-Velasco, IVI-RMA, Madrid, Spain

© 2018 Elsevier Inc. All rights reserved.

Introduction

Endometriosis is one of the most common gynecological disorders and is a condition estrogen-dependant characterized by endometrial tissue located outside of the uterus, most commonly on the ovaries and peritoneum.

Reduced fertility and chronic pain are the two principal clinical features of endometriosis. Endometriosis is one of the main causes of infertility, although the actual relationship between the two is unclear.

The association between severe and advanced endometriosis and reduced fertility may be explained through the severe anatomical and functional abnormalities caused by advanced endometriosis in the female pelvis. The possibility that minimal or mild endometriosis may cause infertility is still a matter of debate.

Epidemiology

The prevalence of endometriosis in women of reproductive age is around 10%. In large studies the prevalence of endometriosis in fertile women appears to be lower (0.5–5%), whereas in infertile women it is higher (25%–40%). Moreover, the rate of infertility has been reported to be six to eight times higher in patients with endometriosis.

Diagnosis Delay

Endometriosis is a chronic and, in most cases, debilitating disease associated with a significant reduction of quality of life due to pain symptoms and/or infertility. In addition, several lines of evidence indicate that a significant number of women with endometriosis do develop comorbidities, such as depressive or anxiety disorders. Delaying the diagnosis of endometriosis clearly aggravates these problems. Early detection is of significant importance because many complications of this chronic disease, such as infertility, may be reversed or treated earlier. Several studies have demonstrated that the length of the time interval from onset of symptoms to diagnosis is surprisingly long (Table 1).

Several factors cause the delay of the diagnosis like widespread use of oral contraceptives that attenuate the symptoms, misdiagnosis, the normalization of menstrual pain, clinical examinations that are nondiscriminatory without transvaginal sonography (TVS), etc.

Risk Factors

Risk factors for endometriosis include obstruction of menstrual outflow (e.g., anatomic anomalies), exposure to drugs (diethylstilbestrol) in utero, prolonged exposure to endogenous estrogen (early menarche, late menopause, or obesity), short menstrual cycles,

Table 1 Diagnostic delay in years from symptoms to diagnosis across different countries

	<i>Diagnosis delay (years)</i>
USA	11.7
UK	7.9
Brazil	7
China	3.3
Italy	10.7
Germany and Austria	10.4
UK and Spain	6.7
Norway	6.7
Ireland and Belgium	4–5

low birth weight, and exposure to endocrine-disrupting chemicals found in various materials such as pesticides, metals, additives or contaminants in food, and personal care products. Twin and family studies suggest a genetic component. Consumption of red meat and trans fats is associated with an increased risk of laparoscopically confirmed endometriosis, and eating fruits, green vegetables, and $n - 3$ long-chain fatty acids is associated with a decreased risk. Prolonged lactation and multiple pregnancies are protective. Endometriosis is associated with increased risks of autoimmune diseases and ovarian endometrioid and clear-cell cancers, as well as other cancers, including non-Hodgkin's lymphoma and melanoma.

Relationship Between Endometriosis and Infertility

The monthly pregnancy rate in women in their mid-reproductive years without endometriosis is around 30%, whereas in those with endometriosis this figure is between only 2% and 10%. This reduced pregnancy rate may even apply to women with minimal endometriosis.

The epidemiological association between endometriosis and low fertility may indicate a causal relationship (Fig. 1), explained by several hypotheses:

- Disorders of ovulation and fertilization, reduced quality of the oocyte and embryo, and dysfunctional implantation.
- Immunological and inflammatory disorders of the peritoneal environment.
- Tubal occlusion
- Disorders of endometrial receptivity, for example due to insufficient hormonal stimulation and progesterone resistance

Diagnosis of Endometriosis

Symptoms

Many symptoms are associated with endometriosis, ranging from pelvic and intestinal complaints to referred pain. The clinician should always suspect endometriosis when any of the following signs are reported by women of reproductive age:

- Pelvic symptoms: pelvic pain typically associated with endometriosis is often intramenstrual (dysmenorrhea), progressive and of variable intensity. Painful sexual intercourse (dyspareunia), abdominal cramping, noncyclical pelvic pain, infertility, fatigue, and weariness are also symptoms of endometriosis.
- Intestinal complaints: periodic bloating, diarrhea/constipation, painful defecation (dyschezia), rectal bleeding.
- Urinary symptoms: pain (dysuria) and/or bleeding (hematuria) when urinating.
- Referred pain: legs, back (specially in adolescents), and shoulder.

Fig. 1 Mechanisms that may link endometriosis with infertility.

Measuring pain is not an easy task because it is very subjective. Questionnaires and quality-of-life scales may be utilized. They may help to assess the impact of pain and treatment response.

Clinical Examination

A clinical examination may indicate endometriosis on the basis of pelvic adhesions that limit movement or cause pain during uterine or ovarian manipulation, ovarian cysts or palpable nodules.

As an important reminder, clinical examination may be inappropriate in some patients (adolescents, sexual abuse victims, certain religious beliefs) and could be very painful in some women. Other technologies could be of help in these situations. In some cases where vaginal exploration cannot be performed, rectal examination may be helpful.

The evidence in the medical literature is weak for diagnosing pelvic endometriosis with physical examination. Ultrasound and magnetic resonance imaging (MRI) technologies are more accurate at diagnosing ovarian and/or deep endometriosis.

Ultrasonography

Transvaginal ultrasound is not useful in the early stage of endometriosis but remains the best technique for diagnosing ovarian cystic endometriosis and it's useful for identifying and ruling out rectal endometriosis but should be performed by clinicians that are highly experienced.

Magnetic Resonance Imaging (MRI)

This is the most appropriate technique for the diagnosis of deep endometriosis, such as rectovaginal, bladder and ureteral forms. Laparoscopy may have blind spots and this is where MRI can have a key role. MRI can help to visualize those areas that may have escaped the laparoscopic field of view. Such areas include the retroperitoneal space or lesions obscured by dense adhesions. MRI may also be helpful to assess response to treatment and the recurrence of disease.

Laparoscopy

Visualization of the lesions outside the uterine cavity during the laparoscopy and histological verification of endometrial glands is the gold standard diagnostic test for pelvic endometriosis.

Controversy exists concerning whether laparoscopy should be performed in all patients when endometriosis is suspected. It could be argued that empirical treatment can be started without a definitive diagnosis, especially in young women or those who are not in need of diagnosis confirmation. Many women will not want to go through surgery if medical treatment relieves the pain. Conversely, arguments to perform a laparoscopy include the patient's wish to have a definitive diagnosis or advanced disease.

In cases of infertility and ovarian endometriosis, laparoscopy should be approached with caution for the procedure may change from a diagnostic tool into an operative event. Surgery, especially before ART treatment, should be envisioned only in specific circumstances.

Biomarkers

By definition, a biomarker is a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes or pharmacological responses to a therapeutic intervention. Many studies have focused on identifying biomarkers on blood or urine samples.

May et al. in a comprehensive two article review cover many molecules that have been studied as potential biomarkers. It is not recommended at present to clinically use biomarkers for the diagnosis of endometriosis. New cytokines and miRNAs are being investigated.

By far, the most studied potential marker has been CA-125. A relationship exists between this marker and the presence of endometriosis. It may not be accurate in early stages of disease to distinguish between presence and absence of disease, but it may have higher accuracy at later stages. It also appears to be more commonly elevated with the presence of an endometrioma, but it is still not currently used to diagnose endometriosis. One potential future use may be for treatment monitoring.

Classification of Endometriosis

The most widely accepted endometriosis classification system is that of the American Society for Reproductive Medicine (ASRM). The scoring is used to determine the stages: I or minimal disease, II or mild, III or moderate and IV or severe disease. This system is based on the location, extent, depth of invasion and aspect of the lesions seen at the laparoscopy. The scoring assigned to each type of lesion is arbitrary and is currently not considered to be properly correlated to the symptoms and activity of the disorder but is useful to determining disease burden and management.

Differential Diagnosis of Endometriosis

Other different conditions of the reproductive tract can cause chronic pelvic pain such as adenomyosis, pelvic adhesions, pelvic inflammatory disease, congenital anomalies of the reproductive tract, and ovarian or tubal masses. It may also be related to other non-gynecologic conditions such as irritable bowel syndrome, interstitial cystitis, fibromyalgia, and other musculoskeletal disorders. A thorough evaluation should be carried out in order to exclude other causes of pain and specially in those women that have not responded with conventional therapy.

Treatment of Infertility Associated With Endometriosis

Medical Treatment

Temporary suppression of ovarian function using antigonadotropic agents is one treatment option for endometriosis-associated pain. However, none has demonstrated any efficacy in the restoration of fertility in infertile patients with endometriosis. The European Society of Human Reproduction and Embryology's *ESHRE guideline for the diagnosis and treatment of endometriosis* states that the suppression of ovarian function to improve fertility in patients with minimal or mild endometriosis is not effective and should not be offered for this indication alone. There is no evidence of its possible efficacy in more advanced stages of the disorder either.

Surgical Treatment

The overall objective of surgery is to excise or coagulate the peritoneal lesions, ovarian cysts, areas of deep endometriosis and adhesions. Laparoscopy is the safest and most effective technique. This procedure, although clearly indicated for the surgical treatment of pain caused by endometriosis, is more questionable for the treatment of infertility. Moderate and severe endometriosis may produce such distortion of the pelvis that restoration of the anatomy may be surgically impossible. Moreover, radical surgery that seeks to remove all endometriotic lesions may be detrimental to the ovarian functional reserve, which is already compromised by the endometriosis itself.

The ESHRE guideline concludes that ablation of endometriotic lesions to improve fertility in cases of minimal to mild endometriosis is more effective than diagnostic laparoscopy alone but there are insufficient clinical trials to determine whether surgical treatment of moderate to severe endometriosis improves the subsequent pregnancy rate. There is also no consensus on the indications for surgical treatment of endometriotic cysts in infertile patients. The presence of an endometriotic cyst in a patient undergoing assisted reproduction could reduce the ovarian reserve and the effectiveness of that treatment.

Combined Medical and Surgical Treatment

It has been proposed that preoperative administration of drugs effective at controlling endometriosis could increase the beneficial effect of surgical treatment on fertility. Medical treatment could facilitate excision, while reducing the surgical trauma, the duration of surgery, the formation of postoperative adhesions and the probability of subsequent recurrence. However, there is no proof that these treatments increase fertility after surgery to a greater extent than surgery alone; therefore their use is not recommended.

Postoperative medical treatment has the advantages of encouraging the involution of residual lesions following surgery and reducing the risk of spreading the disorder associated with intraoperative rupture of endometriomas. However, studies assessing the effect of postoperative treatment on fertility have found no additional benefits to those achieved by surgery alone. The ESHRE guideline therefore concludes that postoperative medical treatment offers no advantages in relation to surgical treatment.

Intrauterine Insemination (IUI)

The presence of endometriosis is thought to reduce the effectiveness of IUI, based on the results of studies in patients treated with artificial insemination using donor semen. This negative effect persists even after the treatment of endometriosis. Several randomized studies show that IUI associated with pharmacological stimulation increases fertility in patients with minimal to mild endometriosis in comparison with expectant management. IUI with ovarian stimulation is effective, but the role of unstimulated IUI is uncertain.

In Vitro Fertilization (IVF)

IVF is an appropriate treatment for patients who have advanced endometriosis with reduced ovarian reserve, or if tubal function is compromised or if there is male factor infertility, and/or other treatments have failed. IVF is the only viable method in cases of severe tubal adhesion-related disease or in the presence of large endometriomas. A recent study concluded that patients with endometriosis-associated infertility have pregnancy rates and birth rates similar to tubal factor controls during IVF treatments. The exception is women with endometriomas, who have lower success rates compared with peritoneal endometriosis and tubal infertility.

Women with endometrioma have a lower mean number of oocyte retrieved and require higher FSH dosage for ovarian stimulation, suggesting that their ovarian reserve is diminished prior to IVF. Women with endometriomas should be counseled regarding their increased risk of cycle cancellation.

When analyzing the impact of endometriosis on uterine environment there was no difference in pregnancy rates between women with endometriosis and tubal factor receiving donor oocytes, suggesting that endometriosis is not detrimental to embryo implantation (26, 27). Recently, we demonstrated that the endometrial receptivity gene signature during the window of implantation is similar in infertile women with and without endometriosis, also for different stages of endometriosis.

Another relevant aspect is whether patients with ovarian endometriosis who are scheduled for IVF would benefit from prior excision of the endometriomas. The chosen procedure should consider the specific condition of each patient, taking into account the likelihood of contributing to ovarian failure through intraoperative destruction of normal tissue, especially in previously operated patients. Whilst surgery did not seem to influence the live birth rate, surgical treatment of endometrioma prior to IVF could exert a further detrimental impact on ovarian reserve. There is therefore not one dogmatic recommendation as to whether women with endometrioma should or should not have surgical intervention prior to IVF.

In summary, there is no evidence that surgical treatment of endometriosis improves ovarian function or enhances the possibility of successful IVF. Based on current evidence, consideration should be given to individualize the care of these patients.

Conclusions

IVF is the most appropriate treatment for infertility in women with endometriosis, especially if there are coexisting causes for the infertility and/or other treatments have failed.

Unfortunately, IVF pregnancy rates are lower in women with endometriosis –oocytes have poorer quality- and diminished ovarian reserve –women with endometriosis produce lower number of oocytes-. Surgical removal of ovarian endometriotic cysts prior to IVF does not offer any additional benefit in terms of fertility outcomes and we should take into account that it could reduce even more the ovarian reserve. Surgery is indicated in cases of pelvic pain when women are young (under 35). Fertility preservation may be considered prior to surgery is ovarian function could be compromised.

Infertility Treatment in PCOS

Ian Waldman and Richard S Legro, Penn State College of Medicine, Hershey, PA, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Since first being described in 1935 by Stein and Leventhal (Stein, 1935), polycystic ovary syndrome (PCOS) is now known to be the most common endocrinopathy in reproductive aged women with multiple medical, metabolic, and reproductive implications. PCOS is a complex heterogeneous disorder and therefore appropriate diagnosis has been debated for many years. The most widely accepted diagnostic criteria are the 2003 Rotterdam criteria, which were subsequently endorsed by the European Society for Human Reproduction and Embryology and the American Society of Reproductive Medicine. The Rotterdam Criteria based the diagnosis of PCOS by the presence of oligo/anovulation, clinical or biochemical signs of hyperandrogenism, and ultrasound evidence of polycystic morphology. Diagnosis is based on the presence of two of the three while excluding other disorders, including Cushing's Syndrome, atypical congenital adrenal hyperplasia, androgen secreting tumors, thyroid disorders, and other disorders causing oligo/anovulation (Group REA-SPcw, 2004).

PCOS is the most common cause of irregular and decreased ovulation, and the most common cause of female infertility affecting 1 in 15 women (Azziz et al., 2004). There is no optimal treatment for infertility in the patient with PCOS and treatment should be individualized based on patient presentation. Optimizing outcome and decreasing risks should be the focus of treatment decision-making, but heterogeneity in study-design, diagnosis, and primary outcome (optimally live-birth rate) make comparisons difficult. This article will review the current treatment options for the infertile patient diagnosed with PCOS.

Life-Style Modification

Obesity is an epidemic worsening throughout the world, but is particularly problematic in the United States, with 38% of women currently afflicted (Ogden et al., 2015). Obesity has been determined to be an independent risk factor for infertility (Sim et al., 2014a; Sim et al., 2014b). As many as 80% of patient's with PCOS in the United States have a concomitant diagnosis of obesity, (Sam, 2007) thus making this an important and growing fertility management issue. The prevalence of obesity among reproductive-aged women is increased in most developed countries around the world.

Weight loss has been recommended as a first line treatment for obese women with infertility prior to attempting other methods of assisted reproductive technology (ART), secondary to the multiple negative effects obesity has on fecundity and fertility (Gesink Law et al., 2007). The implications of obesity are not solely related to infertility, but more significantly to worsening pregnancy outcomes. Obese women were found to have increased rates of stillbirth, gestational diabetes, hypertensive disorders, cesarean delivery, operative vaginal delivery, prolonged labor, shoulder dystocia, fetal neural tube defects, fetal cardiac defects, and neonatal death (Linné, 2004; Cedergren, 2004).

Obese women had a rate of menstrual disturbance three times more frequently than nonobese women and obese women were found to have a greater than $2.5 \times$ higher chance of ovulatory infertility (Norman et al., 2004; Rich-Edwards et al., 1994). Studies have set out to determine if a reduction in weight would lead to improvement in ovulation rates, pregnancy rates, and ultimately live-birth rates.

Studies have shown reasonable goals when recommending weight loss, and found as little as a 5% reduction in current weight, with resumption of ovulation (Crosignani et al., 2003). Likewise, as central adipose tissue is more metabolically active and disruptive to reproduction, a decrease in central adipose tissue improves ovulation rates (Palomba et al., 2008). Just as a decrease in 5% of body weight led to an improvement in ovulatory rates and also to improve pregnancy rates (Crosignani et al., 2003; Kiddy et al., 1992). The primary goal of recommending weight loss prior to attempting pregnancy is to improve pregnancy outcomes, as well as improve live-birth rates. Clark et al., in a prospective trial, found an improvement in miscarriage rate, spontaneous ovulation rate, pregnancy rate, and live birth rate. Women in this study lost an average of 10.2 kg/m^2 (Clark et al., 1998).

In a randomized prospective trial by Legro et al., evaluated preconception intervention with either oral contraceptive pills (OCP), lifestyle modification with a goal of 7% weight loss, or combination of the two. The intensive lifestyle intervention consisted of meal replacements to control caloric intake, antiobesity medication, brief psychological counseling and increase physical activity, indicated that meaningful weight loss can be obtained in a relatively short period (16 weeks) (Fig. 1). They were followed to determine increase in ovulation rates and subsequently live birth rates. Ovulation rates were found to be superior after weight loss with control group ovulatory rates of 46%, lifestyle change 60%, and combination 67%. Live birth rates were not found to be significantly different between the three groups, but after a post-hoc analysis combining the two weight loss groups they approached statistical significance with a *P* value of 0.05 (Legro et al., 2015). In a follow-up study by Legro et al., a secondary analysis of two randomized trials was performed to evaluate immediate treatment with ovulation induction compared with delayed treatment after lifestyle modification. Delaying treatment for lifestyle modification offered a significantly improved ovulation rate and live birth rate (Legro et al., 2016).

Fig. 1 Effects of a 16 week preconception intervention on weight from baseline. Numbers underneath the columns are 95% Confidence intervals. Significant weight loss was achieved with the intensive lifestyle modification with or without the use of oral contraceptives (OCP). From Legro, R. S., Dodson, W. C., Kris-Etherton, P. M., et al. (2015). Randomized controlled trial of preconception interventions in infertile women with polycystic ovary syndrome. *The Journal of Clinical Endocrinology and Metabolism* **100**, 4048–58.

First-Line Treatment

Women with PCOS have a monthly spontaneous ovulation rate of 32%, (Azziz et al., 2001), and often require ovulation induction if lifestyle modification alone does not result in spontaneous pregnancy. There are currently two primary medications by which ovulation induction is executed, clomiphene and letrozole. Letrozole will likely in the near future become the first line treatment for ovulation induction in women with PCOS, but there remain in some countries regulatory barriers to its use. Thus we will begin with clomiphene as a first line therapy. Clomiphene is a selective estrogen receptor modulator (SERM) with partial agonist and antagonist effects. The primary method by which clomiphene works is by antagonistic effects on the hypothalamic estrogen receptors preventing negative feedback resulting in increased secretion of gonadotropin releasing hormone (GnRH) and subsequently altering gonadotropins favorably stimulating ovarian follicular development (Kerin et al., 1985).

Clomiphene has been used since the 1960's for ovulation induction and is considered the first line treatment for ovulation induction (Dickey et al., 1998). Studies have shown ovulation rates of up to 80%, (Messinis, 2005), pregnancy rates up to 60% (Imani et al., 2002), and live birth rates up to 22% (Group TEA-SPCW, 2008). In the Pregnancy in Polycystic Ovary Syndrome I (PPCOS 1) trial, a randomized controlled trial (RCT) found ovulation rates of 49%, pregnancy rates of 30%, and live-birth rates of 23% over six ovulation induction cycles (Legro et al., 2007). It is recommended to move on to a second or third line therapy after six failed cycles of ovulation induction with a single agent (Group TEA-SPCW, 2008).

The standard dose of clomiphene is to initiate with 50 mg/day for 5 days starting on cycle day 2–5 (there is no consensus on which cycle day to begin). This dose can be increased by 50 mg/day up to 150 mg/day and the lowest dose that initiates ovulation should be maintained for the recommended 6 cycles (Group TEA-SPCW, 2008). As many patients with PCOS are anovulatory, many practitioners initiate a menstrual withdrawal bleed with progestin. Cycle initiation with a progestin withdrawal bleed may decrease both pregnancy and live-birth rate, and therefore should not be performed prior to initiation of clomiphene (Diamond et al., 2012). Protocols, such as the stair step protocol advance the dose of clomiphene after a brief period of observation for follicular development without inducing a withdrawal bleed. Empirical evidence thus suggests that in the absence of abnormal bleeding or suspected endometrial pathology, that the dose of clomiphene (or letrozole) can be increased without routine induction of a withdrawal bleed. Of course periodic endometrial cycling is necessary over a longer period of time (3–6 months).

In a recent double blind RCT, Morin-Papunen et al., showed Metformin in combination with clomiphene for ovulation induction with obese and nonobese patients improves pregnancy (13.2% improvement, $P = 0.006$) and live-birth rates (13.1% improvement, $P = 0.014$) compared to placebo. Cox regression analysis showed the addition of metformin increased pregnancy rates 1.6 times (Morin-Papunen et al., 2012).

The most common adverse effects of clomiphene administration is hot flushes, headaches, and visual complaints, but is usually well tolerated (Group TEA-SPCW, 2008). The multiple pregnancy rate has been found to be up to 8% (Liu et al., 2014) and the potential risk of ovarian hyperstimulation syndrome (OHSS) is very low (Group TEA-SPCW, 2008; Brown and Farquhar, 2016).

Letrozole is an aromatase inhibitor that prevents conversion of androgens to estrogens. Its primary action is by suppressing estrogen production, thereby decreasing the negative feedback of estrogens in the hypothalamus leading to increase GnRH production and subsequent ovarian follicular development. The typical starting dose for letrozole is 2.5 mg/day on cycle days 3–7 and if ovulation does not occur, the dose should be increased to 5 mg/day with a maximum dose of 7.5 mg/day. If ovulation is confirmed and pregnancy does not occur, the dose should be repeated for up to 6 subsequent cycles.

Letrozole has been evaluated and initially postulated to have improved outcomes and side-effect profile in comparison to Clomiphene for ovulation induction. In a large RCT by Legro et al., there was found to be a statistically higher ovulation rate by 13.4%, and live birth rate by 8.4%, for Letrozole compared to Clomiphene (Fig. 2). No differences were found in congenital anomalies, pregnancy loss, or multiple pregnancy rates. Letrozole was associated with a higher incidence of fatigue and dizziness compared to Clomiphene (Legro et al., 2014). In a systematic review and meta-analysis, Letrozole was found to have increased

Fig. 2 Kaplan-Meier curves for Live Birth in the PPCOS II trial of letrozole vs. clomiphene. Live-birth rates are shown according to treatment group in Panel A and according to treatment group and maternal body-mass index (BMI, the weight in kilograms divided by the square of the height in meters), in thirds, in Panels B, C, and D. Letrozole improved the live birth rate by 44% over clomiphene with significant improvement or trends toward improvements at all weight classes. From Legro, R. S., Brzyski, R. G., Diamond, M. P., et al. (2014). Letrozole versus clomiphene for infertility in the polycystic ovary syndrome. *The New England Journal of Medicine* 371, 119–129.

live-birth rates and decreased multiple pregnancy rate (Wang et al., 2017). Secondary to these findings, it has been suggested that Letrozole be used as a first line treatment in patients with PCOS for ovulation induction, but as of now, has not officially been adopted by ASRM or ESHRE.

Second-Line Treatment

Clomiphene and Letrozole resistance (i.e., failure to ovulate) is not uncommon among women with PCOS (Imani et al., 1998), affecting approximately 25% of patients challenged with clomiphene and 10% challenged with letrozole. Therefore low dose gonadotropin induction is considered the second-line in medical management for ovulation induction. In a prospective analysis, Eijkemans et al. found a singleton live birth rate of 56% with cumulative live-birth rates of 50% and 71% at 12 and 24 months, respectively (Eijkemans et al., 2003). There are multiple negative effects of gonadotropin induction, including increased risk of OHSS (Swanton et al., 2010), increased multiple pregnancy rates (Legro, 2016), higher cost (Homburg et al., 2012), and increased burden of medication usage, with no oral form available and need for regular ultrasound monitoring. The use of low-dose step-up follicle stimulating hormone (FSH) regimens have resulted in a markedly decreased rate of OHSS, as well as multiple pregnancy rate (Homburg and Howles, 1999).

We have thus far discussed lifestyle modification and medical treatments for the PCOS patient with infertility, but there does exist a surgical option for the clomiphene resistant patient, ovarian drilling. Surgical management for patients with PCOS was first described in the late 1930s by Stein and Leventhal in the form of ovarian wedge resection (CM, 1939), but has since been replaced with laparoscopic ovarian drilling, first described in the 1980s secondary to the concern for postoperative pelvic adhesive disease (Gjønnaess, 1984). Laparoscopic ovarian drilling is performed by creating multiple small perforations with either electrocautery or laser within the ovary. The mechanism of action is not completely understood, but it has been postulated the decrease in ovarian follicles secreting sex steroids decreases the negative feedback on FSH leading to upregulation within the hypothalamus and improved FSH secretion and resumption of ovulation. It is also plausible surgery increases blood flow to the ovaries and increases delivery of gonadotropins, but less likely that it improves insulin sensitivity (Abu Hashim et al., 2013).

In a Cochrane database systematic review of randomized controlled trials, Farquhar et al. evaluated outcomes in patients undergoing laparoscopic ovarian drilling compared with ovulation induction. They found a live-birth rate of 34% with no difference when compared with clomiphene and tamoxifen (a selective estrogen receptor modulator), gonadotropins, or aromatase inhibitors, but decreased compared with clomiphene and metformin. Gonadotropin ovulation induction showed a significantly increased multiple pregnancy rates compared with laparoscopic ovarian drilling. There were no cases of OHSS with ovarian drilling alone, and no difference in clinical pregnancy rates or miscarriage rates with ovarian drilling compared with medical management. There was no difference between unilateral or bilateral drilling with regard to ovulation rate, pregnancy rate, or live birth rate (Farquhar et al., 2012).

In long-term follow-up studies evaluating persistent ovulation rates after ovarian drilling found 7% in patients monitored for 3 years and 38% in those monitored for up to 9 years (Amer et al., 2002). The total pregnancy rate was found to be 82% at 2 years in another study (Felemban et al., 2000). These findings led Nahuis et al. to conclude that laparoscopic ovarian drilling is as effective as gonadotropins for ovulation induction, with the added benefit of decreasing need for other forms of artificial reproductive technology and increasing likelihood of chance for another child (Nahuis et al., 2011).

The major concern in ovarian wedge resection was postoperative adhesion formation and that concern continues for laparoscopic ovarian drilling. In a randomized trial performing second-look laparoscopy after ovarian drilling found ovarian adhesions in 60% of women with no difference in adhesion formation severity by number of drilled holes (Mercorio et al., 2008). The theoretical risk of infertility secondary to tubal occlusion from pelvic adhesive disease is not validated based on the fertility outcomes stated above, but does need adequately powered prospective trials to further elucidate this concern.

In Vitro Fertilization

If first and second line managements are unsuccessful in treating the infertile patient with PCOS, then another form of artificial reproductive technology exists which can be utilized: In vitro fertilization (IVF)/Intracytoplasmic sperm injection (ICSI). IVF/ICSI is the process whereby the ovaries are stimulated to form mature eggs that are ultimately retrieved and fertilized by sperm in the lab. The fertilized embryo is then implanted into the prepared uterus.

There is much debate regarding the ideal treatment method for controlled ovarian hyperstimulation with GnRH agonists having survived the test of time but now being replaced by antagonist protocols in high responders. The debate continues to exist with the significant risk of OHSS primarily in the PCOS patient population (Heijnen et al., 2006). The risk of OHSS is characterized by high rates of abdominal fluid (ascites), pleural and pericardial effusions, hemoconcentration, and electrolyte disorders (Delvigne et al., 1993). The ultimate goal is to improve, or at least maintain, the live-birth rate while decreasing the potential risk for severe OHSS.

The debate continues between agonist vs. antagonist protocols for ovarian hyperstimulation with conflicting reports. GnRH antagonist have begun to be preferred for controlled ovarian hyperstimulation secondary to newer studies and meta-analysis showing no difference in clinical pregnancy rate or abortion rate with a decrease in OHSS (Mancini et al., 2011). Lin et al., in a recent meta-analysis, also found no difference in clinical pregnancy rate and ongoing pregnancy rate in GnRH antagonist protocol while reducing the rate of severe OHSS (Lin et al., 2014). Pundir et al. found no difference in severe OHSS, but when pooled with moderate and severe OHSS there was a significant decrease (Pundir et al., 2012). Al-Inany et al. reported moderate evidence to suggest a decrease in OHSS with an antagonist protocol in a Cochrane review, (Al-Inany et al., 2016), while Singh et al. found similar pregnancy rates, as well as no difference in OHSS (Singh et al., 2014).

On top of the decision to perform an agonist or antagonist cycle, is the decision to undergo final oocyte maturation trigger with the traditionally used human chorionic gonadotropin (HCG) or a GnRH agonist (if using an antagonist protocol). The reason to perform one or the other is to continue to optimize the live-birth rate and attempt to decrease the rate of OHSS. Youssef et al. in a Cochrane review, found a significant decrease in the rate of OHSS when using a GnRH agonist trigger compared to an HCG trigger. The problem with this GnRh trigger are data suggesting a decrease in live-birth rate and ongoing pregnancy rate, while also increasing potential for early miscarriage rate. However these findings were for fresh autologous embryo transfers. When evaluating the data for donor-recipient cycles, there was no difference in live-birth rate or ongoing pregnancy rate (Youssef et al., 2014). This suggests that in a frozen embryo transfer, GnRH agonists could be considered for oocyte maturation without detriment to live-birth rate, while decreasing the risk of OHSS. An insufficient luteal phase was posited as the cause and subsequent treatment has including luteal phase support after GnRh agonist trigger. These observations also led to the hypothesis that elective frozen embryo transfer among high responders, such as women with PCOS may improve live birth rates.

This hypothesis was recently evaluated in a multicenter prospective randomized trial evaluating fresh versus frozen embryo transfers in patients with PCOS. They found a higher live-birth rate mediated primarily through a lower pregnancy loss rate, a markedly decreased risk of OHSS and a higher singleton birthweight among women who were randomized to the elective FET. However there was an increased risk of preeclampsia among these women and a trend toward increased neonatal deaths in the frozen-embryo group, but did not reach statistical significance (Chen et al., 2016). In a Cochrane review including the prior study, they found no difference in live-birth rate, a decrease in OHSS, and decrease in miscarriage rate for frozen embryo transfers compared to traditional IVF/ICSI cycles (Wong et al., 2017). In the Cochrane review, they reported significant risk of bias in the studies analyzed with unclear blinding, unit of analysis error, and absence of adequate termination rules. Secondary to these findings the debate regarding freeze all cycles versus traditional IVF/ICSI in women with PCOS remains, and further high quality studies are needed.

Conclusion

This chapter has reviewed the treatment and current controversies in the polycystic ovary syndrome patient with infertility. Much research is still necessary to optimize outcomes and decrease risks.

ART and Obesity

José Bellver, Instituto Valenciano de Infertilidad, Valencia, Spain

Why the Obese Population Undergoes ARTs more Frequently

Female obesity is related to a three-fold increased risk of subfertility (prolonged time to pregnancy) and infertility (no pregnancy achieved after at least one year of non-protected sexual intercourse). An inverse relationship between female body mass index (BMI) and fecundability has been demonstrated (Wise et al., 2010). Moreover, obesity in adolescence has been associated with a three to four-fold increase in the risk of lifetime nulligravidity and nulliparity (Polotsky et al., 2010). Classically, fertility problems in obese women were related to their high prevalence of ovulatory disorders (Rich-Edwards et al., 2002). However, more recent studies have highlighted that even obese women who present regular menses and ovulation have a reduced probability of conceiving. van der Steeg et al. (2008) showed that per each unit of increase in BMI above 29 kg/m² there was a 4% significant reduction in the cumulative pregnancy rate within a year, the same effect as an additional year of female age. Therefore, infertility in obese women does not seem to be caused only by the presence of disovulation, but also by alterations at the level of the oocyte, embryo and/or endometrium. In this way, obese women are more prone to initiate ARTs than normoweight women. Male overweight and obesity have also been related to increased infertility rates (Nguyen et al., 2007), with the combination of male and female excess weight representing poorer chances of spontaneous conception. Ramblau-Hansen et al. (2007) observed that the odds ratio for subfecundity (defined as time to pregnancy > 12 months) was higher as BMI increased in both men and women, and that this effect was maximum when both members of the couple were obese. In this way, male and female obesity influences natural conception negatively and independently, having an enhanced impact when both are present. Indeed, this is not an infrequent scenario, since partners often share similar lifestyle behaviors.

What Are the Results of ARTs in Obese Population

Many studies agree regarding a lower ovarian response in obese women after ovulation induction or controlled ovarian hyperstimulation (COH) for IVF. Different mechanisms have been implicated in this effect, such as hyperleptinemia, insulin-resistance or the increased volume of distribution of the drug through the body. Thus, the higher the BMI, the lower the ovarian response achieved, regardless of the drug used (clomiphene citrate or gonadotropins) (Bellver et al., 2006). The real question is whether the outcome of assisted conception is impaired by obesity once ovulation has been achieved in ovulation induction treatments or the oocytes have been recovered after COH in IVF.

Low Rank Assisted Conception (Scheduled Intercourse and Intrauterine Insemination)

The results of low rank assisted conception cycles in obese women are controversial. Some studies have reported that the chances of conception are similar to that in normoweight controls (Balén et al., 2006; Souter et al., 2011), but others have described reduced pregnancy rates (White et al. 1996; Koloszar et al., 2002; Al-Azemi et al., 2004). Many patients included in these studies presented polycystic ovary syndrome (PCOS), mild fertility problems -especially anovulation- and low-risk obesity (class I; 30–35 kg/m²), thus having a good prognosis. Therefore, the influence of obesity on reproduction could have been scarce. However, the central distribution of fat seems to be one of the most negative parameters on fertility. In fact, Zaadstra et al. (1993) showed a 30% significant reduction in the chances of patients conceiving after intrauterine insemination per each 0.1 unit of increase in the waist-to-hip ratio.

High Rank Assisted Conceptions (IVF with or without ICSI, and Ovum Donation)

Studies performed on IVF patients are more consistent, showing a significantly poorer outcome in obese women. Bellver et al. (2010) published the largest single center study to date about the influence of female BMI on IVF results, including 6500 IVF cycles with own oocytes. All the parameters of outcome (implantation, pregnancy and live birth rates) were significantly reduced from 30 kg/m² of BMI. Other later multicenter studies have confirmed these findings. Luke et al. (2011) analyzed 45,163 embryo transfers from 345 assisted reproduction clinics in the USA and found a significant reduction in clinical pregnancy and live birth rates as female BMI increased in a dose-dependent manner. Thus, the higher the female BMI, the higher the chances of not achieving a clinical intrauterine gestation or a live born. More recently, Provost et al. (2016a) and Kawwass et al. (2016), with 239,127 and 494,097 IVF cycles with own oocytes, respectively, again reported a significant reduction in clinical pregnancy and live birth rates, and a significant increase in spontaneous abortion rates with a rise in female BMI. To determine whether these results are due to a damage to the embryo or/and endometrium, oocyte donation undoubtedly constitutes the best human model, in which oocytes from healthy young donors controlled for weight are given to recipients with different BMIs. Using this model Cardozo et al. (2016) showed that oocytes from donors in the highest quartile of BMI in their institution (25.3–34.0 kg/m²) resulted in a significant reduction of clinical pregnancy rates in recipients adjusted for BMI, suggesting a deleterious clinical effect of BMI on the oocyte.

Bellver et al. (2013a) analyzed 9587 first cycles of ovum donation in which donors were normoweight. All the outcome parameters (implantation, pregnancy, clinical pregnancy, multiple pregnancy and live birth rates) decreased significantly when the BMI of the recipient was above 30 kg/m². Recently, Provost et al. (2016b) have reported similar results with >22,317 cycles of ovum donation, with outcomes being especially affected from 40 kg/m² of BMI upwards. These reports demonstrate a negative clinical effect of female BMI on endometrial receptivity.

Finally, male obesity also seems to impair IVF outcome. Some studies (Colaci et al., 2012; Petersen et al., 2013) and a recent meta-analysis (Campbell et al., 2015) have described reduced clinical pregnancy and live birth rates in couples in whom the male partner was obese, although the contribution of female BMI to this outcome has not always been adequately controlled.

Why the Results of Spontaneous and Assisted Conception Are Poorer in Obese Patients

Despite the fact that many endocrine and metabolic systemic alterations have been described in obese men and women, as well as local disturbances at the level of the cumulus-oocyte complex, embryo and spermatozoon, no obvious gamete or embryo damage has been described according to the conventional morphological criteria by which their quality is commonly assessed. In fact, despite the abovementioned clinical effects of male obesity on reproduction, no evident alteration of classical parameters of semen (MacDonald et al., 2010; McPherson & Lane, 2015) or sperm DNA fragmentation (Bandel et al., 2015) has been detected. Even in IVF/ICSI studies in which a clear negative effect of male BMI on live birth rates has been observed, no differences in embryo quality have been noted among different ranges of BMI (Colaci et al., 2012). This discrepancy has also been extensively addressed by dozens of studies that have attempted to ascertain the effect of female BMI on oocyte and embryo quality after IVF, but no consensus has been reached. In fact, in a study by Bellver et al. (2010) in which 6500 IVF cycles were included and 81,581 oocytes and their corresponding embryos were analyzed, no correlation was observed between female BMI and embryo quality on day 2 or 3 of embryo development (day of embryo transfer), despite the poorer results obtained in obese women. These findings indicate that the conventional method by which gametes and embryos are assessed in the andrology/IVF lab based on static morphological criteria is inadequate for determining the damage exerted by obesity. In light of this, new methods of assessment have been developed in recent years. Time-lapse analysis was used to evaluate whether the dynamic pattern of embryo division differed in embryos from normoweight or obese women, but no differences were detected (Bellver et al., 2013b). However, more recently, Bellver et al. (2015) observed a different metabolomic profile in the spent culture media of day 3 good quality embryos when the woman was obese, proving that the composition of metabolites that the embryo took from- or excreted into- the culture media was different, with a significant reduction of saturated fatty acids among the identified ones. This suggests that the function of embryos with similar morphology differs according to female BMI, which may account for the clinical results observed.

Table 1 Described consequences of female obesity for IVF results.

<i>Ovarian response</i>
Higher gonadotrophin requirement ("gonadotrophin resistance")
Longer period of ovarian stimulation
Higher cancellation rates
Higher incidence of follicular asynchrony
Lower bioavailability of injected hCG
Decreased periovulatory hCG intrafollicular concentrations
Lower peak of estradiol serum concentrations
<i>Oocytes, embryos and endometrium</i>
Reduced oocyte retrieval
Poorer oocyte quality
Lower mature oocytes
Lower fertilization rates
Poorer embryo quality
Impaired embryo metabolomics (culture media)
Lower incidence of embryo transfer
Lower mean number of transferred embryos
Reduced endometrial receptivity
<i>IVF outcome</i>
Lower implantation rates
Lower pregnancy rates
Higher preclinical miscarriage rates (biochemical pregnancies)
Higher clinical miscarriage rates
Increased risk of fetal defects
Increased complications in 2nd and 3rd trimesters of pregnancy (for mother and fetus)
Lower live birth rates

hCG, human chorionic gonadotrophin; *IVF*, in vitro fertilization.

Regarding the reduction in endometrial receptivity, Bellver et al. (2011) detected a different pattern of gene expression during the window of implantation (WOI; receptive phase of the endometrium) in obese women in comparison to normoweight controls, with a more dysregulated pattern when PCOS was associated. In fact, during the WOI 12 of the 25 genes most related to implantation at that time were expressed in the same way in both obese PCOS women and women with other refractory conditions, such as undergoing COH or carrying an inert intrauterine device. Recently, the same group (Comstock et al., 2017) has analyzed the transcriptomic profile of endometrial gene alterations during the WOI in infertile obese patients, detecting the dysregulation of several genes involved mainly in chemokine, cytokine, and immune system activity and in the structural extracellular matrix and protein-binding molecular functions.

To sum up, obesity impairs spontaneous and assisted conception in men and women, and has a synergistic effect when both members of the couple are obese. A deleterious effect on gametes, embryos and endometrium seems to exist, and is the focus of much current research. The best way to avoid the negative effects of excess weight on fertility is to achieve conception when BMI is below 30 kg/m², and, if possible, below 25 kg/m². This goal can also reduce the increased risk of congenital malformations, maternal and fetal pregnancy complications, and metabolic and non-metabolic diseases in the offspring, all of which are described in obese women.

Table 1 summarizes all the consequences of female obesity in assisted reproduction described in the current literature.

Introduction

Low ovarian responders are considered women who fail to respond to ovarian stimulation and produce an adequate number of follicles and therefore oocytes. Low responders represent a very unique group of patients attending an infertility unit with certain difficulties associated with the diagnostic approach and the optimal treatment they should be offered. Available evidence suggests that they may represent a significant percentage of the population seeking infertility advice, reaching according to reports an incidence of 24% (Ubaldi et al., 2005).

Owing to this increased incidence, it is of paramount importance for the clinician not only to evaluate the etiology associated with low ovarian response, but also to provide a patient-tailored treatment in order to maximize the chances to achieve the delivery of a healthy child.

Etiology and Evaluation of Low Ovarian Response

Age and Low Ovarian Response

Age is probably the strongest element of treatment success in women seeking fertility advice. This is not only associated with decreased oocyte quality and increased aneuploidy rates, but also with the decreased pool of nongrowing follicles with advancing age. Previous reports have shown that the number of nongrowing follicles in the ovaries is dropping and this drop is accelerated after the age of 36 years (Wallace and Kelsey, 2010). Owing to this sequel of events, women of advanced age are at higher risk of experiencing low response to ovarian stimulation and subsequently retrieve fewer oocytes as compared with women of advanced age. Nevertheless, besides that age is apparently a very strong determinant of ovarian response, other factors may modify the association of age with ovarian response. Thus, it is not uncommon to identify excellent ovarian response in women of advanced age with specific phenotypes such as PCOS. Given that previous research has shown that women with PCOS have a delayed age at menopause (Li et al., 2016) and that these patients often present even at the age of 40 with a very good ovarian reserve (Tian et al., 2014), in such cases response to ovarian stimulation can be fairly optimal.

Iatrogenic Interventions and Low Ovarian Response

Ovarian surgery is a key approach of infertility management and has a beneficial effect in women with conditions such as endometriosis. Over the last decades it has been clearly shown that removal of endometriomas in combination with GnRH agonist depot supplementation can minimize the extent of endometriosis-associated inflammation and thus increased the chances of spontaneous pregnancy among infertile couples. Similarly, along with endometriosis, other clinical conditions such as the presence of dermoid cysts or other ovarian benign tumors require surgical management in order to alleviate pain-associated symptoms or due to the risk of malignancy in the future (e.g., borderline ovarian tumors). Still, in spite of the fact that over the years surgical techniques have evolved and sparing fertility ovarian surgery has been of paramount importance, recent evidence proves that such procedures are very often associated with low ovarian response (Raffi et al., 2012). Young women with a previous ovarian surgery often present with a severely diminished low ovarian reserve and thus a high risk to experience low response to stimulation. Consequently, and based on current evidence, the extent and the nature of surgery should always be carefully evaluated and reviewed based on patients' family status (Somigliana et al., 2015). In this context, the decision on whether surgery should be performed avoided or postponed until fertility preservation or family planning has been achieved, needs to be taken based on the risks the benefits of each procedure, but also based on the level of patient's ovarian reserve and age at the moment of the counseling (Somigliana et al., 2015).

Similarly, taking into account the substantial progress made in the treatment of certain malignancies, the percentage of "cancer survivors" has significantly increased over the years. Thus, it is very common to counsel women at their late 30s or early 40s desiring to have a child several years after the treatment of malignant disease. Available evidence demonstrated that chemotherapy and pelvic irradiation may have a severely dramatic reduction in ovarian reserve which unfortunately is irreversible (De Vos et al., 2014). This appears to be strictly associated with the type of chemotherapy used (Anderson and Cameron, 2007) and also with the level of ovarian reserve and the age of the patient at the time of treatment (Dezellus et al., 2017). Taking this into consideration, it is of paramount importance not only for fertility specialists, but also for gynecologists and oncologists to communicate this great risk for all women of reproductive age with a malignant disease requiring treatment and tailor the optimal management plan. Fertility preservation must be offered in these women, either through oocyte vitrification or/and by ovarian cortex cryopreservation, given that many of these patients will be free of disease in the future and may require achieving a pregnancy.

Genetics Causes of Low Ovarian Reserve

Low ovarian response in women of young reproductive age is a finding that should not be overlooked. Although a reduction in ovarian reserve and a low ovarian response should be anticipated with advancing age, occurrence of low response in your reproductive age should be further investigated. According to previous research, a woman whose mother had an early menopause has a sixfold increased risk of having early menopause (Morris et al., 2011; van Asselt et al., 2004), with estimates of this heritability for age at menopause ranging from 30% to 85% (van Asselt et al., 2004). Unfortunately, available evidence suggest that genetic causes can only explain <5% of the variance in the age of menopause (Perry et al., 2013) and thus it should be anticipated that genetic causes will be identified in women of young age who present with low ovarian response. Nevertheless, it is generally accepted that in young patients with low ovarian response further investigation is justified. This should undoubtedly include a karyotype analysis to exclude mainly the presence of any chromosomal abnormality such as Turner syndrome but also genotyping for the detection of FMR1 premutation (Visser et al., 2013; Rohr et al., 2008). Taking into account the higher incidence of impaired ovarian reserve and low ovarian response in these patients (Rohr et al., 2008) but also the consequences that may arise for the offspring from the presence of such genetic conditions, it is of paramount importance to screen patients at risk in order to provide adequate patient management.

Nevertheless, irrespective of the above-mentioned profound aetiological factors associated with low ovarian reserve, in great percentage of low responders the etiology remains unknown.

Assisted Reproduction Technologies of Low Ovarian Responders

Proper management of the low ovarian responder patient should always involve the development of a treatment plan. This not only includes the selection of the appropriate procedure but also the selection treatment protocol specifically tailored for each patient.

Intrauterine Insemination or Ovarian Stimulation for In Vitro Fertilization

The decision on whether low responders should be offered intrauterine insemination or IVF is apparently related to several factors such as the male partner sperm quality, the duration of infertility and of course the age of the woman. Although in young poor responders IUI could be the first treatment option in case of normospermia and a short duration of infertility, it is rather uncertain whether we shall proceed to such an approach in women of advanced age. A recent RCT has clearly shown that in women above 40 years old one cycle of IVF results in significantly higher pregnancy rates compared with three cycles of IUI and a shorter time to pregnancy (Goldman et al., 2014). Thus in these cases IVF should be the optimal procedure. Furthermore, we always need to take into consideration the level of ovarian reserve prior to proceeding (Freeman et al., 2012). Consequently, it may be considered more appropriate to proceed with IVF in women with very low AMH levels, even if they are younger, simply because evidence clearly demonstrate that these women have a higher risk of entering early menopause compared with women with normal AMH levels (Freeman et al., 2012).

Ovarian Stimulation Protocols for In Vitro Fertilization

Over the last 20 years several different stimulation protocols have been utilized for the treatment of poor ovarian responders. Still, despite the vast body of literature, it appears that treatment of poor ovarian responders always remains a burden for the clinician.

Downregulation protocol

The type of downregulation protocol has always been an issue of interest, with investigators supporting the advantage of one versus other. Despite that GnRH antagonists have been introduced into clinical practice much later, initially they were frequently introduced in poor ovarian responders. Today following the publication of several clinical trials it seems rather unlikely that the type of protocol plays a role for poor ovarian responders. Metaanalysis published in 2006 showed no difference either when comparing short flare-up agonist or long GnRH agonist protocol versus GnRH antagonist (Griesinger et al., 2006), whereas a more recent meta-analysis replicated the results by Griesinger (Xiao et al., 2013).

Type of gonadotropins

Similarly, the type of gonadotropin used does not appear to have any effect on the final reproductive outcome. Although several studies supported that potentially the use of LH activity may improve pregnancy rates in women of advanced reproductive age (Gizzo et al., 2015; Revelli et al., 2012), the most recent randomized controlled trial has shown that the addition of rLH to rFSH does not increase pregnancy rates in poor ovarian responders (Humaidan et al., 2017).

In the same context, recent cohort studies have clearly shown that the prognosis in poor ovarian responders fulfilling the Bologna criteria for poor response (Ferraretti et al., 2011) is always poor, with very low pregnancy rates irrespective of the type of gonadotropin used (Polyzos et al., 2014; Busnelli et al., 2015; La Marca et al., 2015).

Gonadotropin starting dose

Controversy regarding the appropriate starting dose is frequent among treating clinicians. Others believe that mild ovarian stimulation should be the aim for this difficult group of patients whereas others are proponents of strong stimulation with very high doses.

The current literature strongly supports that doses above 300 IU appear to be futile since no difference can be seen in pregnancy and live birth rates in women treated with very high doses ([Berkkanoglu and Ozgur, 2010](#); [Lefebvre et al., 2015](#)). Thus, the use of such doses is not recommended. Furthermore, a recent randomized study demonstrated that mild stimulation results in comparable results with high starting FSH doses ([Youssef et al., 2017](#)). Still, we certainly need to be cautious, especially in women who may have a good functional ovarian reserve with a good antral follicle count and had a previous low ovarian response. Given that we do have enough evidence now to demonstrate that cumulative live birth rates significantly increase with the number of oocytes ([Drakopoulos et al., 2016](#)) in such kind of patients with a good antral follicle count it may be more clinically relevant to aim to the maximum number of oocytes retrieved.

Natural Cycle IVF

Natural cycle IVF has been traditionally considered the valid treatment option for poor ovarian responders with very low functional reserve. In such women with very low antral follicle count, ovarian stimulation definitely has no actual role simply because there are no follicles to stimulate and recruit. Although natural cycle can be considered an option for the treatment of these patients, women should be aware that the anticipated outcome should be rather low. A large recent retrospective cohort in poor ovarian responders according to the Bologna criteria ([Ferraretti et al., 2011](#)) demonstrated disappointingly low live birth rates, significantly lowers compared with the outcome of natural cycle IVF in normal ovarian responders ([Polyzos et al., 2012](#)).

Accumulation of Oocytes

The strategy of accumulating oocytes in order to increase the outcome in poor ovarian responders has also been analyzed over the years. Although such an approach is a preferred strategy by many clinicians, we need to underscore that apparently the available evidence is rather weak. Based on the study by Cobo et al., it seems that potentially accumulation might be superior to only a fresh IVF cycle ([Cobo et al., 2012](#)), results should be interpreted with caution. The reason is not only the fact that results in that study appear comparable between accumulation and fresh embryo transfer in women less than 40 years old, but also because the patients sample in women more than 40 years old was limited.

Adjuvant Therapies

Owing to the disappointing results of most ovarian stimulation protocols in low ovarian responders, research has focused on adjuvant therapies, prior to or during ovarian stimulation in an attempt to increase the recruitable follicular cohort. The use of androgens and growth hormone has been the most wide used regimens. Although results from metaanalysis appeared promising, the body of available evidence is very small and the protocols used lack uniformity regarding the actual dose and duration of administration ([Gonzalez-Comadran et al., 2012](#); [Kolibianakis et al., 2009](#)).

Growth hormone

Early experimental studies have shown that growth hormone (GH) administration can stimulate the production of insulin-like growth factor (IGF) ([Doldi et al., 1996](#)). Thus, owing to the synergistic effects of IGF-1 with FSH on follicular development ([Adashi, 1992](#)), many hypothesizes that GH could stimulates follicular development and in this context increase oocyte quality. Results of randomized trials favored GH supplementation during ovarian stimulation with metaanalysis of randomized trials demonstrating that GH can increase pregnancy rates in low responders ([Kolibianakis et al., 2009](#)) and an updated metaanalysis 4 years later providing similar results with a three times higher odds for a pregnancy in favor of GH administration ([Duffy et al., 2010](#)). Nevertheless, the sample size of all trials was very limited and the quality not adequate in order to justify routine clinical use, especially taking into consideration the lack of safety data and its increased cost.

Androgen pretreatment

Androgen pretreatment in low responders undergoing IVF/ICSI has also been investigated as an option to increase the recruitable follicular.

Owing to early studies in primates demonstrating that testosterone can increase the number of primary follicles and the FSH receptor expression ([Vendola et al., 1998, 1999a,b](#); [Weil et al., 1998, 1999](#)) research has focused on the use of androgens in women with poor ovarian response. Although initial reports have shown that DHEA may be promising in these women, the most recent RCTs failed to show any improvement in pregnancy rates in poor responders as compared with placebo ([Yeung et al., 2014](#)).

On the contrary, data for testosterone appear to be rather more promising with early RCTs showing an increase in pregnancy rates compared with placebo or no treatment ([Gonzalez-Comadran et al., 2012](#)). Still, evidence is limited, sample sizes small and the optimal dose and duration of testosterone administration remains to be determined. Available evidence from animal

experiments and testosterone pharmacokinetics suggest administration of ~2 months of testosterone prior to initiation of ovarian stimulation at a dose around 5.5 mg per day and a multinational RCT is ongoing in order to provide clear evidence regarding the role of testosterone in low responder patients (Polyzos et al., 2016).

Conclusion

The diagnostic and therapeutic management of low ovarian responders remains one of the most challenging tasks for every clinician. Appropriate diagnostic approach and analysis of the etiological factors of diminished ovarian reserve and low response to stimulation is always essential as an initial approach for these women. Selection of treatment strategy is equally important and always should be associated with the level of ovarian reserve of the patient the age and the duration of the infertility. Although most of the available treatment protocols appear to be equally “ineffective” in low responders, functional ovarian reserve and the number of recruitable follicles should always guide the decision of the protocol selection. In women with low functional reserve current options are rather limited given that ovarian stimulation is unlikely to change the prognosis in these women. Future research on adjuvant supplementation, such as testosterone, prior to ovarian stimulation is needed in order to demonstrate whether such an approach can alter the prognosis of these women or whether oocyte donation should be the only realistic option for low ovarian responders with severely limited ovarian reserve.

Introduction

Assisted reproductive techniques (ART) form the cornerstone for the management of infertility that includes male factor infertility, anovulatory causes, diminished ovarian reserve, tubal factor, endometriosis, and unexplained infertility (NICE, 2016). Controlled ovarian stimulation is the mainstay of IVF cycles to increase the pool of oocytes and subsequently embryos. Approximately, 1.5 million ART cycles per year have been reported and this number is expected to increase (ESHRE, 2016). Due to the significant variation in response to gonadotropins, reproductive endocrinologists have a significant interest in optimizing outcomes success rates and reducing the risk of ovarian hyperstimulation in patients.

Definition and Risk Factors

The definition of high responders helps designing the appropriate stimulation protocol, reducing the risk of OHSS, and plan appropriate interventions. While the Bologna criteria have been adopted for the poor responder patients, no such definition exists for high responders (Mascarenhas and Balen, 2017). That said, two criteria have been use: the first is serum estradiol > 6000 pg/mL on the day of trigger while the second is > 30 oocytes retrieved (Mascarenhas and Balen, 2017). When either one of these risk factors was present, there was a 33% chance of developing severe OHSS; however, if both risk factors were present, the risk of developing severe OHSS was 80%. Similarly, different cut-offs have also been used for serum estradiol levels on the day of trigger including 3000 and 4000 pg/mL. In 2002, Papageorgiou et al. included serum estradiol levels from 461 cycles in women aged < 35 years and defined high response as the 90th centile corresponding to 3444 pg/mL in their study. Reproductive Technology (SART) registry-based retrospective cohort study concluded that above a threshold of 15 oocytes, there is an increased risk of OHSS but a plateauing of live birth rate (Steward et al., 2015). In 2014, Arce and La Macra published a retrospective analysis revealing that potential high-responders were defined as having an initial anti-Müllerian hormone (AMH) value > 75th percentile (5.2 ng/mL). Arce et al. concluded that AFC and AMH are very sensitive markers of ovarian reserve identified to date, and are ideal in planning personalized stimulation protocols. These sensitive markers permit prediction of the ovarian response with reliable accuracy (Arce et al., 2014). Markers of ovarian reserve, in particular AMH and AFC, are critical in identifying those women who are likely to show a high response to controlled ovarian response. The diagnostic accuracy of basal AMH level for the prediction of OHSS has been shown to be good and comparable to the estradiol levels or number of ovarian follicles on the day of hCG administration (Lee et al., 2008), thus allowing for its use in routine clinical practice for preventative strategies. An AMH cutoff of 3.36 ng/mL had 90% sensitivity and 81% specificity for predicting OHSS (Lee et al., 2008). (Table 1)

Young women have a higher degree of ovarian responsiveness, which could explain the higher risk of hyper-response. Follicle-stimulating hormone (FSH) receptor polymorphisms also could influence ovarian response with activating mutations predisposing to hyper-response and inactivating mutations leading to infertility (Rizk, 2009).

According to the Royal College of Obstetrics and Gynecology, there are several predictors or risk factors for high response and they are the following (Royal College of Obstetrics and Gynecology, 2016) (Table 2):

Table 1 Importance of markers of high responder

<i>Risk factors for high responder</i>	<i>Importance</i>
AMH	+++
AFC	+++
FSH	++
Number of oocytes retrieved	++
Estradiol level	++
Age	+

+, Not very appropriate.

+++, very appropriate.

1. Previous history of OHSS
2. High antral follicle count (AFC). An antral follicle count (AFC) >20 correlates with a higher risk of OHSS (8 is for poor responders).
3. The presence of polycystic ovaries.
4. High anti-Mullerian hormone (AMH) levels. An AMH cutoff of 3.36 ng/mL had 90% sensitivity and 81% specificity for predicting OHSS.
5. Young age
6. Low body mass index (BMI)

Management of the High Responder

Because ovarian response is determined by the dose of gonadotropins, individualizing the dose of gonadotropins according to patient characteristics and risks factors is crucial to reduce the risk of hyper stimulation while still ensuring the retrieval of multiple oocytes. Many authors have published multiple dosing algorithms. [La Marca et al. \(2012, 2013\)](#) have published three normograms: the first including age and AFC, the second including age, AFC and FSH ([La Marca et al., 2013](#)) and third including age, AMH and FSH ([La Marca et al., 2012](#)). Another meta-analysis suggested that the optimal daily recombinant FSH stimulation dose is 150 IU/day in normal responders younger than 39 years undergoing IVF. Compared with higher doses, this dose is associated with a slightly lower oocyte yield, but similar pregnancy rates and embryo cryopreservation rates ([Sterrenburg et al., 2010](#)).

Other treatments have been studied in high responder patients to help reduce the risks. Such treatments include the following:

1. Metformin ([Mascarenhas and Balen, 2017](#))
2. Albumin ([Mascarenhas and Balen, 2017](#))
3. Hydroxyethyl starch ([Mascarenhas and Balen, 2017](#))
4. Cabergoline ([Mascarenhas and Balen, 2017](#))
5. Vascular endothelial growth factor blockers ([Mascarenhas and Balen, 2017](#))

Monitoring the ovarian response during ovarian stimulation allows providers to adjust the dosage of gonadotropins. Using GnRH antagonist-based protocols results in a 50% reduction in OHSS compared to long agonist protocols ([Toftager et al., 2016](#)). Also using GnRH antagonist cycles enables the use of a GnRH agonist, rather than hCG, as a trigger for final oocyte maturation. This will result in significant decrease in the risk of OHSS however, at the expense of a reduced pregnancy rate ([Youssef et al., 2014](#)), though recent data on using a low dose of HCG-add back (1500 IU every 3 days) resulted in comparable success rates ([Humaidan et al., 2013](#)). Two other techniques have emerged to help reduce the risks in the high responder patient. The first is segmentation of the IVF cycle, and the second is utilizing a modified luteal phase after agonist triggering to overcome the luteal phase deficiency.

The segmentation approach (also known as freeze-all) is best explained by routine use of antagonist cycles with GnRH agonist triggering followed by elective cryopreservation of oocytes or embryos and transferring them later in a frozen embryo transfer cycle.

Table 2 Risk factors for hyper response

<i>Risk factors</i>
Young age (RCOG, 2016)
Low BMI (RCOG, 2016)
High AMH (Arce et al., 2014)
High AFC (La Macra et al., 2013)
PCOS (Mascarenhas et al., 2017)
High serum estradiol (Steward et al., 2015 ; Papageorgiou et al., 2002)
Multiple follicles during the ovarian stimulation (Steward et al., 2015)

While reducing the risk of OHSS in the high responder patient, this approach results in longer time to pregnancy and increased cost (Devroey et al., 2011).

The utilization of luteal phase support after agonist triggering can help optimizing the luteal phase through intensive hormonal support with estrogen and progesterone or low dose hCG (Griffin et al., 2012).

Coasting is another technique used in high responder patients. This technique involves the temporary withdrawal of gonadotropins while continuing ovarian suppression for no more than 4 days while waiting a fall in serum estradiol levels. While there was a reduction in the mean number of oocytes retrieved, the clinical pregnancy and live birth rate were not affected (D'Angelo et al., 2011). Coasting however has been largely replaced by the above two treatment modalities.

In a large randomized control study including 1050 women allocated to either short GnRH antagonist or long GnRH agonist protocol, Toftager et al. concluded that the short GnRH antagonist protocol should be the protocol of choice for patients undergoing their first ART cycle in females younger than 40 years of age including both low and high responders. Patients at risk of OHSS particularly benefit from the short GnRH antagonist treatment with a 50% reduction compared to the long agonist protocol (Toftager et al., 2016).

Conclusions

High response to gonadotropins is a risk factor for ovarian stimulation for ART. In addition to the risk of OHSS, high response can adversely impact endometrial receptivity. The uses of GnRH agonists for triggering and segmental approach (freeze all) have been very effective in reducing the risk of OHSS. This has resulted in safer treatments of hyper responders without compromising the success rate of ART.

COMPLICATIONS

Hemoperitoneum After Oocyte Retrieval and Severe Pelvic Infection

Raoul Orvieto, Sheba (Tel-Hashomer) Medical Center, Ramat Gan, Israel; and Tel-Aviv University, Tel-Aviv, Israel

© 2018 Elsevier Inc. All rights reserved.

Transvaginal ultrasound-guided aspiration of oocytes is a well-accepted and universally used method in assisted reproduction (Dicker et al., 1993). Its major advantages include easy access to ovarian follicles with excellent oocyte yield and good visualization of the major pelvic vessels. It is done as a day care procedure, either under intravenous analgesia and sedation or under general anesthesia, and is usually traumatic.

Nevertheless, there are some inherent risks, namely, puncture of blood vessels and hemoperitoneum, bleeding from the vaginal-vault puncture site, rupture of adnexal cystic masses, bowel perforation, trauma to pelvic organs, and pelvic infection. Maxwell et al. (2008) have reported on the incidence of both serious and minor complications in young women undergoing 886 oocyte retrievals for oocyte donation. While the rate of serious complications, which included ovarian hyperstimulation syndrome, ovarian torsion, infection, and ruptured ovarian cyst, was 0.7%, the rate of minor complications severe enough to prompt the donor to seek medical attention after retrieval was 8.5%.

The aim of the present article is to discuss comprehensively two of these complications: bleeding and pelvic infection.

Bleeding

During ultrasound-guided transvaginal oocyte aspiration, multiple punctures of the vaginal vault, or inappropriate handling and rotation of the ultrasound vaginal probe while inserting an aspiration needle through the vaginal vault can injure or tear the vaginal mucosa, ovaries, intra-abdominal organs, or blood vessels (Dicker et al., 1993; Tureck et al., 1993; Lenz et al., 1987; Wikland et al., 2011). Bleeding from the vaginal vault is a common consequence of ovum pick-up (OPU), with a reported incidence of 1.4%–18.4% (Tureck et al., 1993). The use of a thinner-tipped needle (0.9 mm in diameter) during OPU resulted in a significantly less vaginal bleeding (Lenz et al., 1987). In most cases, vaginal bleeding as a result of OPU stops spontaneously (Wikland et al., 2011). In cases where a local pressure with a sponge forceps or vaginal packing with a large gauze roll could not stop bleeding, suturing is required.

Intraperitoneal or Retroperitoneal Bleeding

Transvaginal oocyte aspiration can also cause bleeding if intraperitoneal or retroperitoneal pelvic blood vessels are injured or if there is damage to the fine vascular network surrounding the punctured ovarian follicle. The reported incidence of severe intra- or retroperitoneal bleeding varies from 0% to 1.3% (Dicker et al., 1993; Wikland et al., 2011; Aragona et al., 2011); Sauer (2001) reported on one case of intra-abdominal bleeding complicating aspiration of 1000 oocyte donors. Young, lean patients, those with polycystic ovary syndrome (PCOS) or a history of previous surgery were specifically demonstrated to be at much higher risk for this complication (Liberty et al., 2010; Zhen et al., 2010). Intraperitoneal bleeding tends to be severe with acute hemodynamic deterioration, whereas retroperitoneal bleeding usually has a later and more indolent presentation. Yih et al. (2001) studied serial complete blood counts before and after OPU in 93 in vitro fertilization (IVF) cycles and demonstrated a nonsignificant change in hematocrit levels, indicating that a clinically significant blood loss after OPU is actually uncommon.

Azem et al. (2000) described a patient who presented to the emergency room 10 h after OPU with severe lower abdominal pain, vomiting, and tenesmus. Examination revealed a distended abdomen with severe tenderness in the pouch of Douglas; on transvaginal sonography, a minimal, 3–4 cm collection of fluid was noted. Laparoscopy followed by laparotomy, which was performed on the basis of the clinical profile, revealed a retroperitoneal hematoma 7 cm in diameter. After evacuation and hemostasis, active bleeding from the mid-sacral vein occurred and was controlled by a metal clip. This case demonstrates the indolent course of retroperitoneal bleeding and physicians should be alerted to the possibility of retroperitoneal hematoma despite an absence of free fluid in the pouch of Douglas. Of notice, similar case with no significant intraperitoneal fluid collection was also described as a result from ureteral injury with the consequent uroretroperitoneum (Fiori et al., 2006).

Intraabdominal bleeding should be suspected immediately after OPU on the development of signs and symptoms of anemia—specifically, weakness, dizziness, dyspnea, or persistent tachycardia. Early management consists of intense hemodynamic monitoring, together with serial measurement of blood hemoglobin concentrations and ultrasonographic evaluation for the presence of intra-abdominal fluid. It should be emphasized, however, that intra-abdominal blood clots or retroperitoneal bleeding might be invisible even to an experienced ultrasound operator. A drop in hemoglobin concentration is an indication for prompt blood transfusion. If hemodynamic deterioration continues or acute abdominal pain develops, diagnostic laparoscopy or exploratory

laparotomy with subsequent hemostasis of the bleeding site(s) are required. The clinician must make sure to handle the fragile hyperstimulated ovaries very cautiously. Of notice, a longer time interval between OPU and surgical intervention was noted to put the patient at risk of ovariectomy (Nouri et al., 2014).

Dicker et al. (1993) described three cases of severe intra-abdominal bleeding from ovarian puncture sites during OPU, leading to acute abdominal complications. In two of the patients, symptoms developed 3 h after OPU (hemoglobin 9.0 g/100 mL and 8.1 g/100 mL, respectively), and laparoscopic drainage and hemostasis were sufficient. The third patient became symptomatic after 4 h (hemoglobin 7.3 g/100 mL) and required exploratory laparotomy and hemostasis in addition to the transfusion of four units of blood as a life-saving procedure. Later, Battaglia et al. (2001) reported severe intra-abdominal bleeding from the surface of both ovaries in a patient with coagulation factor XI deficiency. As expected, the patient became symptomatic 3 h after OPU and required laparotomy, partial resection of stuffed ovaries, and hemostasis. Physicians should be aware of the presence of concomitant coagulopathy and might therefore consider intense coagulation-factor replacement before or during abdominal exploration.

Massive delayed intra-abdominal hemorrhage was also reported following OPU (2 and 4 days later), in patients at risk for thromboembolic event, who concomitantly used therapeutic dose of low molecular weight heparin (LMWH) (Mashiach et al., 2013). These cases should direct physicians' attention and keep them alert, while conducting an IVF treatment to this subgroup of patients. Moreover, the authors recommended that the patient be kept in the ward for observation for at least 2–4 days following OPU.

Prevention and Treatment

Can we prevent severe intra-abdominal bleeding from ovarian puncture sites during OPU? In a cross-sectional retrospective study, Revel et al. (2011) questioned the utility of coagulation screening before OPU. Among the 1032 patients evaluated, they found that 534 coagulation tests were needed to prevent one case of bleeding associated with an abnormal coagulation test result. Moreover, while the use of color Doppler sonography during OPU was suggested to reduce the risk of blood vessel injury by the guiding needle (Shalev et al., 2004), its routine use could not predict all cases with moderate peritoneal bleeding.

Description of the intraoperative measures needed to control intra-abdominal hemorrhage is beyond the scope of this text, and the reader is referred elsewhere for a detailed review.

Pelvic Infection

Pelvic inflammatory disease (PID) is an infrequent complication of ultrasound-guided transvaginal aspiration of oocytes or ET, with a reported incidence of 0.2%–0.5% per cycle (Howe et al., 1988; Ashkenazi et al., 1994; Al-Kuran et al., 2008). Signs or symptoms of pelvic infection, such as pyrexia, continuous low abdominal pain, dysuria, or offensive vaginal discharge, are infrequent (Howe et al., 1988). However, this does not exclude occult, subclinical bacterial colonization, which may influence the success of the IVF–ET treatment, or slowly progress throughout pregnancy (Al-Kuran et al., 2008). Ashkenazi et al. (1994) evaluated the outcome of all IVF–ET procedures performed in their unit between 1986 and 1992. Of the 4771 patients who underwent transvaginal OPU, 28 (0.58%) had symptoms of PID within 1–7 days. The diagnosis was established by a rise in body temperature to 38°C for more than 48 h, signs of pelvic peritonitis on physical examination, leukocyte count of $> 12,000$ cells/ m^3 , and elevated erythrocyte sedimentation rate. All patients were admitted to hospital for treatment with intravenous antibiotics. Of notice, ovarian abscess following oocyte retrieval may manifest late during pregnancy with low grade fever or vague abdominal pain.

OPU can also lead to severe abdominal complications. Our group reported on nine patients (0.24%) with tubo-ovarian or pelvic abscess after transvaginal-guided OPU (Ashkenazi et al., 1994). Three patients required laparotomy and adnexectomy, whereas in six patients, culdocentesis was performed for adequate pelvic abscess drainage. Kelada and Ghani (2007) have described a case of bilateral ovarian abscesses following transvaginal oocyte retrieval, complicated by early signs of consumption coagulopathy. The latter is a serious and life-threatening complication of pelvic infection and sepsis, which should be diagnosed and corrected immediately.

Mechanisms Underlying Pelvic Infection

During transvaginal aspiration, accidental needle transport of cervicovaginal flora into ovarian tissue can cause unilateral or bilateral oophoritis, and accidental puncture of a contaminated or sterile hydrosalpinx can cause salpingitis. Some authors have attributed pelvic infection to infected endometriotic cysts or tuboovarian abscess after aspiration of endometriomas, or, rarely, to inadvertent puncture of the bowel. Pelvic infection in women with endometriosis was shown to be more serious and resistant to antibiotic treatment, and frequently required surgical intervention (Elizur et al., 2014). Pelvic infection can occur as a direct consequence of transcervical ET. This is evidenced by reported cases of PID following ET in an agonadal donor-egg recipient, or during cryopreserved ET (Friedler et al., 1996); it may also occur as a result of the reaction of a silent or persistent subclinical infection, as seen occasionally after hysterosalpingography. Another possible cause during ET is catheterization of the uterus, which may force bacteria-laden air or fluid into one or both tubes by a piston-like effect.

Effect of Acute Pelvic Infection on IVF–ET Outcome

The first study of the impact of pelvic infection on IVF–ET outcome was reported by [Ashkenazi et al. \(1994\)](#). We found that the number of oocytes recovered, fertilized, and cleaved in 28 patients undergoing IVF in whom PID developed was similar to that of a comparison group with mechanical infertility. However, there were no pregnancies in the PID group, as compared with the 23%–31% pregnancy rate per transfer in the whole group of patients treated by IVF, indicating that the appearance of PID at the critical time of implantation may cause a failure to conceive. This finding has several possible explanations, such as endotoxemia, the local inflammatory reaction or temperature elevation ([Ben-Rafael and Orvieto, 1992](#)).

Treatment

The potential for intraperitoneal bacterial contamination during transvaginal oocyte recovery is well known and has led to the routine use of prophylactic antibiotics and vaginal disinfection. [Meldrum \(1989\)](#) found no case of pelvic infection among 88 transvaginal retrievals with the use of intravenous cefazolin and vaginal preparation with povidone–iodine and saline irrigation; nor did [Tsai et al. \(2005\)](#) in patients with ovarian endometrioma, using only vaginal douching with aqueous povidone–iodine followed by normal saline irrigation. [Borlum and Maiggard \(1989\)](#) reported on two cases of serious pelvic infection in almost 400 transvaginal aspirations. They used only two vaginal douchings with sterile saline and noted that minimizing the number of repeated vaginal penetrations may have helped in lowering the risk of infection. However, the appropriate type of antibiotic administration, timing or duration of therapy, and the efficacy of therapy have not yet been established. Indeed, some authors claim that these measures may not only further reduce the incidence of PID after oocyte retrieval, but can even increase the risks of both an adverse reaction and of colonization with resistant organisms. Our experience with vaginal douchings with sterile saline in approximately 1100–1200 OPIs per year revealed a very low rate of PID after OPI. [Peters et al. \(1993\)](#) suggested that only women with a tubal abnormality and a history of pelvic infection should receive prophylactic antibiotics before oocyte aspiration, and also possibly after ET. Others have suggested that such patients may benefit from transabdominal or transvesical rather than transvaginal procedures ([Wren and Parson, 1989](#)).

It is also noteworthy that [Egbase et al. \(1999\)](#), in a study of the effect of prophylactic antibiotics in OPI on the endocervical microbial inoculation of the endometrium at ET, found that prophylactic antibiotics not only reduced the number of positive microbiology cultures of embryo catheter tips, but also significantly increased implantation and clinical pregnancy rates. On the other hand, in their prospective randomized study, [Peikrishvili et al. \(2004\)](#) could not demonstrate any beneficial effects of antibiotic prescription (amoxicillin & clavulanic acid 1 g/125 mg) for 6 days following oocyte retrieval on implantation, pregnancy, or miscarriage rates.

Pelvic inflammatory disease or tubo-ovarian abscess after OPI require accurate diagnosis and prompt treatment with broad-spectrum antibiotics. In the presence of a pelvic abscess that is larger than 8 cm or unresponsive to medication, transvaginal or percutaneous drainage is the treatment of choice, with or without ultrasound-guided intracavitary instillation of a combination of antibiotics. Patients who received antibiotics alone are more likely to require further surgical intervention when compared with patients who additionally received image-guided drainage ([To et al., 2014](#)). Sometimes surgical laparoscopy or laparotomy is needed to evacuate the abscess or remove the infected tubes or adnexae.

In summary, the appearance of PID at the critical time of implantation results in failure to conceive. This effect may be mediated by bacterial endotoxins, a local inflammatory reaction against bacteria with the involvement of cytokines that affect implantation and early embryonic development, or temperature elevation that directly affects the conceptus. Although the role of prophylactic antibiotics is still controversial, they can be considered in the presence of risk factors for PID; aspiration of hydrosalpinx or endometriomas during OPI might be a risk factor for infection and should be avoided. Furthermore, to prevent total failure, if PID develops before ET, cryopreservation and ET in subsequent cycles should be considered. However, if PID develops after ET, the bacterial infection and fever should be treated rigorously to prevent reproductive failure.

Glossary

Ectopic pregnancy A pregnancy implanted at an abnormal location outside the normal uterine cavity, most commonly within the Fallopian tube in women.

Heterotopic pregnancy Concurrent intrauterine and ectopic pregnancy.

Human chorionic gonadotrophin The hormone produced by the trophoblast cells of the placenta; essential to maintain progesterone output from the corpus luteum in early pregnancy and detected in maternal blood or urine in a pregnancy test.

Laparoscopy Minimally invasive (keyhole) surgery where access to and visualization of the abdominal/pelvic cavity is achieved using an endoscope (telescope).

Laparotomy A large incision through the abdominal wall into the abdominal cavity.

Salpingectomy Surgical removal of a Fallopian tube.

Salpingostomy Incision in a Fallopian tube wall.

Nomenclature

ART Artificial reproductive technology

β -hCG Beta subunit of human chorionic gonadotrophin ("pregnancy hormone")

EP Ectopic pregnancy

FT Fallopian tube

HP Heterotopic pregnancy

IUP Intrauterine pregnancy

IVF In vitro fertilization

TVUSS Transvaginal ultrasound scan

Introduction

Ectopic pregnancy (EP) occurs when an embryo implants and develops outside of the endometrial-lined uterine cavity. The name derives from the Greek "ektopos" meaning "out-of-place" and was first described in AD 963 by Islamic surgeon Albucasis. In women, 1%–2% of all pregnancies are ectopic and in 95%–98% of cases, the pregnancy occurs in the Fallopian tube (FT; Fig. 1). Rarely, EPs develop at or in the utero-tubal junction (interstitial or cornual), ovary, cervix, myometrium, abdominal cavity or in a caesarean section scar. They are also occasionally bilateral. In respect to abdominal EPs, implantation to almost any mesentery, organ or ligamentous structure (including the broad ligament) has been described. Cornual pregnancies are a slight

Fig. 1 Image of a tubal ectopic pregnancy taken at laparoscopy.

Fig. 2 Heterotopic pregnancy.

misnomer as they occur within an endometrial-lined cavity but this is within a developmentally abnormal uterus. EPs are almost exclusively incompatible with a live neonate, except in occasional cases of abdominal and caesarean section scar EPs. However, all EPs risk serious maternal morbidity, if not mortality, largely as a result of associated intraabdominal hemorrhage. In tubal EP, presence of hemorrhage is often referred to as a “ruptured” EP. This description is misleading as hemorrhage is more often a result of gradual trophoblast invasion of maternal vasculature and destruction of the tube wall as opposed to sudden tubal dehiscence. This article will focus on EPs in women but it is important to note that this phenomenon also occurs, although rarely, in other mammalian species (e.g., in rabbits, guinea pigs, and other primates). However, EPs in these species are almost exclusively abdominal, with only a small number of tubal pregnancies reported in other primates (Corpa, 2006). Heterotopic pregnancy (HP) refers to concurrent ectopic and intrauterine pregnancy (IUP) (Fig. 2). HP is essentially a rare variant of EP and presents similar diagnostic difficulties and management dilemmas as with other rare forms of EP (Talbot et al., 2011).

Incidence and Mortality

Globally, the incidence of EP has risen in the last few decades. However, it is likely this is largely due to improved detection and increased reporting. The Eighth Report of the Confidential Enquiries into Maternal Deaths in the United Kingdom covering the triennium 2006–2008, provides the most recent estimate of EP incidence in the UK at 11 per 1000 pregnancies (equivalent to 12,000 EPs per year). The incidence of HP is low at 1:25,000–30,000, except following ART where incidence is approximately 1%. The global incidence of EP is hard to estimate due to regional differences in registering of births and varying use of live birth (in lower income countries) or total number of pregnancies (Western world) as a denominator. Underreporting is probable in resource poor areas as the diagnosis can be missed or misclassified (in particular spontaneously resolving EPs will likely go unidentified) (Leke et al., 2004). In these lower resource countries the incidence is thought to be higher, at least partially attributed to increased prevalence of untreated sexually transmitted infections (Masha et al., 2017). In the UK, the most recent MBRRACE (Mothers and Babies: Reducing Risk through Audits and Confidential Enquires) report identified 12 women who died from early-pregnancy causes and in 9 of these cases cause of death was EP. In low resource countries, the majority of women present with ruptured EPs due to a lack of early pregnancy care, and as a result mortality is higher.

Etiology and Pathophysiology

The majority of tubal EPs are located in the ampulla (~70%) perhaps not surprisingly, as the fertilized embryo spends the majority of tubal transit time in this region. Other tubal EPs occur in the isthmus (~12%) or infundibulum/fimbria (~11%) (Bouyer et al., 2002). Currently, the ovary is the next most common site for EPs. The etiology of ovarian EP is largely unknown. Interstitial and cornual EPs deserve special mention as 33% present with rupture and they carry a 2%–2.5% mortality rate, much higher than other EPs. The terms interstitial and cornual EP are often used synonymously in the literature but they describe two separate entities. Interstitial EPs develop within the 1–2 cm uterine portion of the FT which lies within the thick muscular wall of the uterus. Cornual EPs are within an endometrial lined cavity but this is within a developmentally abnormal uterus (bicornuate, unicornuate, or septate), such that ongoing pregnancy is associated with uterine rupture. Intramural pregnancies carry the same risk of uterine rupture but are extremely rare, occurring at the site of previous myomectomy. Abdominal EPs result from retrograde efflux of an embryo or an unfertilized oocyte into the peritoneal cavity prior to implantation or follow expulsion of an implanted tubal EP through a breach in the FT wall. With the rise in caesarean deliveries and improved ultrasound resolution, the incidence of caesarean scar EPs has increased over the last few decades to 1:1800–2200. These pregnancies implant in the

endometrial- and myometrial-deficient scar tissue at the site of the previous uterine incision. Due to their scarcity, the natural history of caesarean scar EP is uncertain but there appears to be some overlap with placenta accreta. There are some reported cases of misdiagnosis or intentional pregnancy continuation with resulting emergency caesarean hysterectomy and delivery of a live, albeit premature, infant. However, uterine rupture is inevitable and most rupture before viability with serious associated maternal morbidity.

The development of tubal EPs are largely attributed to FT damage or dysfunction, although uterine and embryonic factors may also be involved (particularly in the case of IVF where physiological passage of the embryo through the FT is bypassed) (Shaw et al., 2010). Although epidemiological studies have identified strong correlations between certain risk factors and EP the causal mechanisms behind these correlations have not been fully elucidated. There exists a “chicken and egg” scenario as it is not possible, for obvious ethical and practical reasons, to discover if alterations in gene or protein expression in ex-vivo EP samples predisposed to, or resulted from, EP. Moreover, in up to 50% of cases, no risk factor is identified. Anything that can cause anatomical distortion or inflammation within the FT can pre-dispose to EP, for example, pelvic infection (particularly *Chlamydia trachomatis*), previous EP or previous tubal surgery. It is supposed that damage to the FT creates a proinflammatory environment, exposing extracellular matrix and cell adhesion proteins, which can encourage aberrant blastocyst attachment. In addition, functional alterations within the endothelial cilia, smooth muscle or tubal secretions that transport the embryo towards the uterus can lead to EP, such as those induced by cigarette smoking. Other risk factors associated with EP include: abdominal surgery (e.g., appendectomy, caesarean section), subfertility, IVF, endometriosis, advancing maternal age (particularly >35 years) or conception on contraception (intrauterine devices, the oral contraceptive pill, the morning after pill). In regards HP (EP in the presence of ongoing IUP), the single biggest risk factor is ART, particularly related to multiple embryo transfer following IVF or ovarian stimulation. Within this group, the same preexisting risk factors apply as for EP. As with EP, the extrauterine pregnancy in HP is most commonly tubal, although cervical, caesarean scar and even triplet pregnancy with tubal and cervical EP have been reported.

Clinical Presentation and Diagnosis

A diagnosis of EP/HP should be considered in any woman of reproductive age presenting with collapse (hypovolemic shock) and anemia, regardless of knowledge of pregnancy status. Indeed, in half of the UK cases of maternal mortality reported between 2009 and 2014, there was delay in initial diagnosis in the face of these signs. A “FAST” (Focused Assessment by Sonography for Trauma) scan and a catheter β -hCG test can quickly establish a diagnosis in the case of haemodynamic instability. In the Western world, the majority of EP/HPs present subacutely with one, some or none of the following symptoms:

- acute abdominal or pelvic pain that is often but not exclusively unilateral,
- vaginal spotting or bleeding,
- gastrointestinal disturbance (diarrhea/vomiting),
- dizziness,
- shoulder tip pain (resulting from diaphragmatic irritation).

Some of these symptoms may also indicate miscarriage, ongoing viable intrauterine pregnancy (IUP) or maybe unrelated to pregnancy (e.g., appendicitis). However, in all women of reproductive age with symptoms possibly related to EP/HP, an initial urinary β -hCG test is cheap, quick and vital. If positive, this can be followed with quantitative maternal serum β -hCG measurement and a transvaginal ultrasound scan (TVUSS).

TVUSS has a sensitivity of 87%–99% and a specificity of 94%–99% for diagnosis of EP (Elson et al., 2016). It is now so sensitive that a gestational sac at a diameter of <3 mm can be identified. A TVUSS in early pregnancy should include examination of the cervical canal, interstitial portions of the FT, both adenexa and the pouch of Douglas (to identify free fluid, indicating blood, in the peritoneal cavity) (Jurkovic and Mavrelos, 2007). Regardless of anatomical location, the majority of EPs appear as a heterogeneous solid swelling. It is less common to see a gestational sac +/- yolk sack and even rarer to see a fetus +/- cardiac activity. Occasionally a “pseudosac” is seen in the endometrial cavity and can be misdiagnosed as an IUP. This pregnancy-induced fluid accumulation can be differentiated from an IUP as it is centrally as opposed to eccentrically placed, does not contain a yolk sac and is not surrounded by a hyperechoic ring of decidua. A “textbook” TVUSS of a tubal EP identifies an empty uterus with an adenexal mass that moves separate to the ovary (“sliding sign”). This sign is absent in ovarian EP, where a clue to diagnosis is additional identification of a separate corpus luteum. Cervical EPs can be detected by identification of a “barrel shaped” cervix with a mass below the level of the internal os. Caesarean section scar EPs are often in a similar location, but will be anterior with thin or absent myometrium between the gestation and the bladder. In both instances it is important to identify surrounding color doppler flow to exclude a miscarrying gestation. Interstitial pregnancies can be differentiated from those within the uterine cavity as they are completely encased by myometrium. It should also be possible to identify the pregnancy at the lateral aspect of the “interstitial line” (a thin hyperechoic line representing the interstitial portion of the FT, extending from the uterine cavity through the myometrium). In cornual pregnancies, there may only be one “interstitial line” seen if the uterus is unicornuate. The gestational sac will be surrounded by myometrium but, in contrast to an interstitial pregnancy, there will be communication with the intrauterine cavity seen on TVUSS. Where a pregnancy is developing within a rudimentary horn, this will be seen separate and mobile from the uterus, perhaps attached by a vascular pedicle. In some cases, where accurate diagnosis by TVUSS is difficult (e.g., multifibroid uterus with distortion of the endometrial cavity) or detailed anatomical delineation for surgical planning is required, a magnetic resonance image should be obtained.

TVUSS is the investigation of choice to identify an EP and can detect an EP even at very low serum β -hCG levels. This is due to the aberrant nature of β -hCG secretion in an EP which is not necessarily related to the size of mass on TVUSS. As such, TVUSS should be undertaken regardless of β -hCG if EP is considered. That said, an IUP, if present, is only likely to be detected if β -hCG is > 1000 – 2000 IU/L. Where there is no obvious intra- or extrauterine pregnancy on TVUSS, the pregnancy is of unknown location (PUL) and serial serum β -hCG measures become important. PUL is a working diagnosis reached at first assessment in approximately 10% of women presenting with symptoms in early pregnancy. The differentials in this case include: ongoing IUP, failing IUP or EP. In a normal IUP, maternal serum β -hCG levels typically increase by $> 66\%$ in a 48 h period and IUP can then be confirmed by TVUSS. In EP or failing IUP, serum β -hCG levels can rise suboptimally, remain roughly static or fall. Serial β -hCG measures every 48 h, repeat TVUSS and repeat clinical assessments are required to reach a diagnosis. On some occasions, where it is difficult to differentiate between a failing IUP and an EP, inpatient monitoring may be necessary and sometimes an endometrial biopsy is obtained to identify if placental tissue (villi) are present within the uterine cavity, suggesting an IUP. Ultimately, diagnostic laparoscopy, with a view to treatment if an EP is positively identified, may be required. As yet there is no single biochemical test that can definitively identify an EP, nor discriminate between a failing IUP and an EP. Progesterone is sometimes included alongside β -hCG in assessment of women with possible EP but does not add any predictive power and is not recommended (Cartwright et al., 2009).

In HP, where, in the presence of an IUP seen on TVUSS, there is question about a concurrent EP, serial serum β -hCG measures are unhelpful as aberrant β -hCG production by an EP is masked by the IUP. In these cases, repeat TVUSS and in some cases MRI, is required. HP is a dangerous condition as detection of an IUP can distract from the presence of a concurrent EP. Symptoms that, in a woman of reproductive age, might signal an EP, such as pain and bleeding, are attributed to the IUP. A cystic adnexal mass on ultrasound may be discounted as a corpus luteum. As the majority of cases of HP follow ART, it is fortunate that a population of patients at risk of HP can be identified in which intensive monitoring is possible and already undertaken. However, in the general population, it is important to “think ectopic” if symptoms persist even if an IUP is identified.

Management of Tubal EP

Tubal EP can be managed surgically, medically or expectantly, depending on patient parameters and patient preference.

Surgical Treatment

Historically, EP had an extremely high mortality rate. Edinburgh born, Robert Lawson Tait, was the first surgeon to successfully perform salpingectomy for ruptured tubal EP. He was meticulous regarding sepsis (unusual at the time) and from 1883 he performed over 40 laparotomies with salpingectomy with only one maternal death. Over the next century, survival rates for EP improved dramatically with the advent of blood transfusion, urinary and serum β -hCG detection and ultrasound. Today, the majority of women with EP will still be managed surgically. In particular, surgery (following initial resuscitation) is the only safe treatment when a woman presents with haemodynamic compromise. Surgical management in a stable patient is also the only option if the current criteria for medical or expectant management (see below) are not met or the patient chooses surgical treatment. A laparoscopic approach is preferred, where surgical skills and equipment are available and the women’s clinical condition allows. Laparoscopy is associated with less postoperative pain, fewer complications, quicker recovery and shorter hospital stay than laparotomy. There has been much debate as to whether surgical removal of the tube containing the EP (salpingectomy) or evacuation of the products of conception through an incision in the tube (salpingostomy) has the best outcome in terms of future fertility. In a randomized controlled trial, salpingostomy, as opposed to salpingectomy, did not significantly improve future fertility prospects in women with a healthy contralateral tube (Mol et al., 2014). As salpingectomy is associated with fewer complications (e.g., bleeding from the tube) and does not require postoperative β -hCG monitoring to ensure resolution of residual trophoblast (present in 8% of cases), it is now the preferred approach in most instances. Salpingostomy or medical treatment is generally preferred in women with contralateral tubal disease unless they only plan to pursue IVF. In this instance, where presence of damaged tubes may reduce embryo implantation rate, increase early pregnancy loss and increase risk of EP, bilateral salpingectomy is sometimes performed after careful consultation. Tubal reanastomosis (following removal of the tubal segment containing the EP) has a high rate of EP recurrence and is not recommended. Clinical consensus of the NICE Ectopic Pregnancy and Miscarriage guideline development group is to recommend anti-D rhesus prophylaxis following surgery for EP or significant maternal hemorrhage.

Medical Treatment

Intramuscular methotrexate is currently the only medical treatment for EP. Methotrexate inhibits dihydrofolate reductase, preventing reduction of dihydrofolate to tetrahydrofolate; the latter is a requirement for purine and pyrimidine production during DNA synthesis. In 1956, Roy Hertz used methotrexate to treat choriocarcinoma. This was the first successful use of chemotherapy to cure a solid tumor. In the 1980s, high- and multiple-dose methotrexate regimes, with folinic acid supplementation, were used to treat tubal EPs. We now use a lower- and single-dose of 50 mg/m^2 without folinic acid supplementation, to treat small tubal EPs. Serum β -hCG is measured on days 1, 4, 7, 11, and weekly thereafter until β -hCG is < 15 IU/L (as tubal rupture has not been reported below this level). A 15% drop in β -hCG between days 4 and 7 has a positive predictive value for treatment success of 93%. If this

drop does not occur a further dose of methotrexate is administered. Resolution of the EP takes 2–7 weeks. This regime is based on a clinical trial by [Stovall and Ling \(1993\)](#) in 120 EP patients and is successful in 88% of cases. Where β -hCG does not decline or tubal rupture occurs (sometimes even despite a declining β -hCG) surgery is required. Although other protocols have been suggested, no well-powered comparative trials have been performed. Based on a few small trials, oral or direct intragestational injection have similar efficacy to intramuscular methotrexate but have, respectively, more side effects or are more invasive and are therefore not favored.

Methotrexate is inexpensive but, due to the follow-up required, only becomes cost effective in comparison with laparoscopic surgery when β -hCG is <1500 IU/L ([Mol et al., 2008](#)). It is cost neutral when β -hCG is <3000 IU/L and in most units this is the cut-off for methotrexate treatment of EP. Clinically, however, 80%–90% success rates are reported up to 5000 IU/L. Other ultrasound criteria must be met: tubal mass <3.5 cm diameter (larger masses can indicate intragestational hemorrhage); minimal free fluid on TVUSS; no fetal cardiac activity (as this increases treatment failure rate) and exclusion of a concurrent IUP. Clinically, the woman must be haemodynamically stable and report minimal pain. She must not be breastfeeding nor taking any medications that might interact with methotrexate and should be advised to avoid alcohol and sexual intercourse during treatment. A full blood count, liver and renal function are obtained before treatment to rule out any coincident infection; liver, renal, or hematological disorder; or immunodeficiency. Low dose methotrexate causes nonspecific abdominal pain in two thirds of women and rarely stomatitis, conjunctivitis or UV related dermatitis. Theoretically, myelotoxicity and acute respiratory distress syndrome are possible but unlikely using the “single-dose” protocol. Unfortunately randomized control trials comparing treatment success and effects on future fertility of single-dose intramuscular methotrexate with salpingectomy are lacking (most previous studies have compared with salpingostomy +/- methotrexate at the time of surgery). Information from retrospective cohort studies suggest salpingectomy may be associated with lower fertility rates than salpingostomy or methotrexate, but there is inevitable selection bias as salpingectomy is the treatment of choice in women with intraabdominal hemorrhage and larger EPs. Recent studies suggest combining methotrexate with the EGFR antagonist, gefitinib, may reduce the need for surgery and decrease the time to β -hCG resolution ([Skubisz et al., 2013](#)).

Expectant Management

As with IUPs, some EPs will resolve spontaneously. A recent prospective observational study has suggested that as many as 30% of EPs presenting to a UK early pregnancy unit will spontaneously resolve ([Mavrelos et al., 2013](#)). The authors conclude that women with a β -hCG below 1500 IU/L, EP <3 cm on USS, no haemoperitoneum, no or minimal abdominal pain and no fetal cardiac activity can be safely managed expectantly until serum β -hCG is negligible with a 71% success rate. Failure was most often due to a rising β -hCG, although 8% of women experienced worsening pain or intraperitoneal bleeding. These women did not require blood transfusion but this highlights the absolute necessity of easy access to healthcare, patient attendance for monitoring and patient understanding of the signs of tubal hemorrhage when considering expectant management. Where this is achievable, this option can be offered to eligible women. However, an economic assessment of expectant management in comparison with methotrexate or surgical treatment is yet to be performed. This is necessary given the requirement for frequent monitoring, and the increased failure rate in comparison with methotrexate. In addition, good quality evidence is currently lacking examining EP recurrence and IUP rates following expectant management.

Management of HP

The majority of HPs are managed surgically, ideally by laparoscopy, without instrumentation, and with minimal handling of the uterus. Salpingectomy is likely preferable over salpingostomy as the operation is easier, there are less complications and the situation does not permit monitoring for residual trophoblast. The rate of ongoing IUP in HP following treatment of the EP is about 60%. Systemic methotrexate is not offered in HP due to teratogenicity concerns and risk to viability of the IUP. Ultrasound guided potassium chloride/hypertonic solution injection into the gestational sac and/or aspiration is sometimes used in cornual or interstitial HPs where it is preferable to radical surgery.

Management of Nontubal EP

Rare forms of EP require personalized management strategies based on expert opinion as only case reports and small case cohorts exist in the literature. An ongoing Cochrane review may provide some evidence base for interventions in future ([Shen et al., 2014](#)). Surgical resection, preferably by laparoscopy is preferred in ovarian EP (wedge resection, partial, or complete oophorectomy), cornual and interstitial EP (cornuostomy, cornual resection, or hysterectomy) and abdominal pregnancies (ligation/embolisation of blood supply +/- removal of EP). Concurrent uterine embolisation in the case of cornual, interstitial or caesarean scar EP is often prudent and may allow for hysteroscopic or laparoscopic removal. Adjuvant methotrexate, either empirically or in the case of persistently high β -hCG postoperatively, can be a useful addition to surgery. Primary treatment with systemic methotrexate may reduce morbidity and improve fertility prospects where surgical treatment risks significant blood loss/hysterectomy such as in cornual, cervical, and caesarean scar EP. One study using single-dose intramuscular methotrexate for women with cornual pregnancy and with β -hCG <5000 IU/L, regardless of presence of fetal heart beat, was successful in 16/17 patients. Failure rate increases

with β -hCG > 10,000 IU/L but some success in multidose regimes, particularly in the case of caesarean scar EP, has been reported. As with surgical management of these rare variants of EP, the risk of sudden, significant hemorrhage despite medical treatment is present. Haemostatic techniques such as balloon tamponade and cervical cerclage may minimize this risk but occasionally emergency “rescue” surgery is required. Expectant management is only very occasionally undertaken where initial β -hCG is very low and declining.

Following Treatment

The psychological impact of EP on a woman or couple can be considerable. In the acute situation it can be easy to forget that these patients have lost a pregnancy and will experience the emotions associated with a miscarriage in addition to dealing with difficult decisions regarding treatment, implications for future fertility, and perhaps significant morbidity. Patient associations such as The Ectopic Pregnancy Trust can provide evidence-based information and support to those affected by EP. Women should be advised to expect bleeding or spotting that can last up to 6 weeks after treatment for EP. For most women, it is possible to advise that IUP rates following methotrexate, salpingectomy, or salpingostomy are 60%–80% within the following 2 years with a 5%–20% chance of EP recurrence. Women can try to conceive again as soon as they feel ready, except following methotrexate where women should be advised to avoid conception for 3 months due to concerns about teratogenicity. Following uterine surgery the advice should be tailored to the individual but is generally 3–6 months.

Conclusions and Future Research Directions

Worldwide, EP is still a leading cause of maternal morbidity and mortality in early pregnancy. Although it is possible, in about 50% of cases, to retrospectively identify specific risk factors, in most instances, screening for EP in early pregnancy is only instigated if the patient has previously suffered an EP. Research is required to understand the mechanisms behind the recognized epidemiological associations, but this is inhibited by the difficulty in differentiating cause from effect and the lack of an animal model of EP. Improvements in management of EP over the last few decades have attempted to minimize morbidity associated with treatments and maximize future reproductive potential. With the development of more potent therapeutics for EP (e.g., combination therapy with gefitinib), medical treatment may become the gold standard treatment for stable EP in future. However, improvements in management are hampered by the lack of a noninvasive diagnostic test for EP in early pregnancy and resultant diagnostic delays. A simple, cheap test with good sensitivity and specificity has the biggest potential to make a difference to outcomes for this condition. In the absence of that, improved periconception and early antenatal care is vital to reduce maternal morbidity and mortality, particularly in low resource countries.

Nomenclature

β-hCG (beta-hCG) It is a quantitative blood test to measure the level of human chorionic gonadotropin hormone (hCG) in the body. hCG is produced from the syncytiotrophoblast cells of pregnancy.

Introduction

“...I recall nothing which in times past has caused me more anxiety and doubt, or in regard to which I have found it more difficult to get any satisfactory rules from books, than the treatment of abortion.”

—T.G. Thomas, 1908.

Assisted reproductive technology (ART) is defined as all interventions that include the in vitro handling of both human oocytes and sperm or of embryos for the purpose of reproduction. This includes, but is not limited to, in vitro fertilization (IVF) and embryo transfer (ET), intracytoplasmic sperm injection (ICSI), embryo biopsy, preimplantation genetic testing (PGT), assisted hatching, gamete intrafallopian transfer (GIFT), zygote intrafallopian transfer, gamete and embryo cryopreservation, semen, oocyte and embryo donation, and gestational carrier cycles (Zegers-Hochschild et al., 2017).

For a woman or a couple hoping to have a child through ART, a positive pregnancy test seems like the first hurdle crossed in what will be a very long journey. Thus when after the first few days, the couple is told that the pregnancy has “failed,” there are numerous psychological repercussions that a patient goes through, along with the physical and clinical.

It is thus important to understand what miscarriage is, so as to know what can be done to prevent it.

Nomenclature

The word *abortion* is derived from the Latin word *aboriri*, which means to miscarry.

According to The International Glossary on Infertility and Fertility Care (2017), a spontaneous miscarriage/abortion is defined as spontaneous loss of an intra-uterine pregnancy prior to 22 completed weeks of gestational age (Zegers-Hochschild et al., 2017).

Different nomenclature defining events associated with early pregnancy and miscarriage described in Table 1.

Incidence

In natural cycles, up to 55% of conceptions are estimated to be lost due to implantation failure or pre-clinical (biochemical) miscarriage and approximately 15% lost in clinical miscarriage (Macklon, 2002). In a recent study by Boomsma et al. (2009) it was shown that in stimulated cycles, the contribution of implantation failure for the numbers of conception losses is higher (50%) than described for natural cycles (30%) while pre-clinical (biochemical losses) and clinical miscarriage is approximately 15% and 10%, respectively.

While reviewing other literature, biochemical pregnancy loss rate is 27% (54/200) after frozen embryo transfer (ET) and 22.1% (122/500) after fresh ET. Clinical abortion rate is 14.5% after frozen ET and 9% after fresh ET (Aflatoonian et al., 2010).

When reviewing the incidence based on type of oocyte and embryos, the incidence of clinical miscarriage in patients after transferring embryos using self-oocytes, donor-oocytes and vitrified-warmed embryos are 15.9%, 21.8%, and 25.2%, respectively (Banker et al., 2016).

If we look at the incidence of miscarriage following ART in different registries: according to Australian & New Zealand Assisted Reproduction Database (ANZARD) (2015) out of the 17,659 clinical pregnancies, 79.9% resulted in a delivery and 19.0% resulted in clinical miscarriage. The outcomes of 193 (1.1%) clinical pregnancies were not known because women could not be followed up or contacted by fertility centers.

According to FIVNAT registry (2015), out of 2149 pregnancies, 525 (24%) had spontaneous miscarriage.

Table 1 Nomenclature describing early pregnancy events

<i>Nomenclature</i>	<i>Definition</i>
Biochemical pregnancy (preclinical spontaneous abortion/miscarriage)	A pregnancy diagnosed only by the detection of HCG in serum or urine and that does not develop into a clinical pregnancy (Zegers-Hochschild et al., 2009)
Clinical miscarriage	Intrauterine pregnancy demise confirmed by ultrasound or histology (ASRM Practice Committee, 2013; Stephenson and Kutteh, 2007)
i. First-trimester miscarriage	Intrauterine pregnancy demise before 12 weeks of gestational age
Early miscarriage	Intrauterine pregnancy loss of < 10 weeks size on ultrasound (Kolte et al., 2014)
• Anembryonic miscarriage	Intrauterine pregnancy loss with a gestational sac but without a yolk sac or an embryo on ultrasound
• Yolk sac miscarriage	Intrauterine pregnancy loss with a gestational sac and yolk sac, without an embryo on ultrasound
• Embryonic miscarriage	Intrauterine pregnancy loss with an embryo without cardiac activity on ultrasound
Fetal miscarriage	Intrauterine pregnancy loss ≥ 10 weeks size with a fetus (≥ 33 mm) on ultrasound (Stephenson and Kutteh, 2007)
ii. Second-trimester miscarriage	Intrauterine pregnancy loss after 12 weeks of gestational age
Vanishing sac(s) or embryo(s)	Spontaneous disappearance of one or more gestational sacs or embryos in an ongoing pregnancy, documented by ultrasound (Zegers-Hochschild et al., 2017)

Miscarriage Types

Broadly, miscarriages are of two types: biochemical and clinical miscarriages.

Biochemical Miscarriage

Spontaneous pregnancy demise based on decreasing serum or urinary b-hCG levels, without an ultrasound evaluation.

In the general population, most cases of biochemical pregnancy remain undetected. Thus the incidence is different for these cases as compared to patients undergoing assisted reproductive treatment. In the latter group, more stringent monitoring and early testing allows us to detect transient β -hCG rises which would otherwise have been missed (Annan et al., 2013).

Numerous studies have advocated that ovarian stimulation alters the endometrial receptivity, hence increasing biochemical pregnancy rates (Kasius et al., 2014).

But a study by Zeadna et al. (2015) attempts to dispel this theory. Their study showed fertile controls who conceived spontaneously has a higher biochemical pregnancy rate (18%) as compared to women undergoing fresh or frozen embryo transfers (13.8%).

A study by Yang et al. (2015) reviewed over 10,000 cycles to show that biochemical pregnancy in the first IVF cycle is a negative predictor for future positive results.

Etiology (Annan et al., 2013)

The exact etiology of biochemical miscarriage after ART is unknown.

Numerous factors have been implicated:

1. Genetically abnormal embryos
2. Poor endometrial receptivity
3. Genetically abnormal oocyte
4. Sperm DNA damage
5. Stress

Pathogenesis

Soon after fertilization, or embryo transfer, the embryo begins to secrete β -hCG. The amount of β -hCG continues to rise as the trophoblastic reaction and embryo invasion continues. Hence a patient tests positive for pregnancy at this early stage. However, in case of a biochemical miscarriage, further growth of the embryo stops, thus preventing any clinical evidence of the pregnancy to be visible on ultrasound (Annan et al., 2013).

Clinical Miscarriage

A pregnancy which can be visualised on ultrasound is known as a clinical pregnancy. A spontaneous loss of this type of intra-uterine pregnancy prior to 22 completed weeks of gestational age is known as spontaneous miscarriage/abortion (Zegers-Hochschild et al., 2017).

Broadly, there are two types of clinical miscarriage (Fig. 1):

- i. First trimester miscarriage
- ii. Mid-trimester miscarriage

Types

- i. First trimester miscarriage (Kolte et al., 2014):

Spontaneous pregnancy demise before 12 weeks of gestational age is called first trimester miscarriage.

This can be divided into two parts: early miscarriage and fetal miscarriage

- Early miscarriage:

Early miscarriage is defined as intrauterine pregnancy loss of < 10 weeks size on ultrasound and it is divided in to three categories:

- (a) *Anembryonic miscarriage*:

It is an intrauterine pregnancy loss with a gestational sac but without a yolk sac or an embryo on ultrasound. In this case, the trophoblast has invaded the decidua but the embryonic disc has not developed.

- (b) *Yolk sac miscarriage*:

Intrauterine pregnancy loss with a gestational sac and yolk sac, without an embryo on ultrasound.

- (c) *Embryonic miscarriage*:

It is an intrauterine pregnancy loss with an embryo without cardiac activity on ultrasound.

- Fetal miscarriage:

It is defined as pregnancy loss ≥ 10 weeks size with a fetus (≥ 33 mm) on ultrasound.

- ii. Mid-trimester miscarriage:

Miscarriage/abortion resulting after 12 weeks of gestation is defined as mid-trimester miscarriage.

Etiopathogenesis of clinical miscarriage following ART

Causes/factors related to ART

1. *Ovarian stimulation*:

The use of exogenous gonadotrophins for controlled ovarian hyperstimulation (COH) as part of IVF has become a well-accepted practice; however, this can have an impact on oocyte and embryo quality and endometrial receptivity.

Early research suggested that the exposure of the developing oocyte to supraphysiological concentrations of gonadotrophins may disturb oocyte maturation and the completion of meiosis leading to chromosomal aneuploid oocytes and/or embryos (Hodges et al., 2002). Whereas animal studies seem to support an association between FSH exposure and embryonic aneuploidy, human studies have been more conflicting.

Possible mechanisms suggested either FSH-induced chromosome dysfunction in oocytes or recruitment of poorer-quality oocytes when the process of naturally selecting a dominant follicle is overridden with ovarian stimulation. If exogenous FSH

Fig. 1 Types of clinical miscarriage.

increases aneuploidy, it could lead to an increased miscarriage rate in patients undergoing IVF, because most miscarriages are the result of chromosomal abnormalities (Andersen et al., 2000; Lathi et al., 2007). But, Massie et al. (2011) concluded that the incidence of embryonic aneuploidy was not higher in pregnancies conceived with FSH stimulation compared with spontaneous conceptions in infertility patients. This suggests that exogenous gonadotrophins exposure does not increase the risk of aneuploidy.

Multiple ovarian follicle maturation by COH will produce supraphysiological serum estradiol (E2) levels that may induce morphologic (Kolb et al., 1997) and biochemical (Simón et al., 1996) endometrial alterations related to uterine receptivity without affecting embryo quality. Thus, with high E2 concentration, implantation and LBR (live birth rate) decreases without affecting miscarriage rate (Ji et al., 2013).

2. *Number of oocytes retrieved:*

There was a strong association between the number of oocytes retrieved and the clinical miscarriage rate. The miscarriage rate fell from 20% to 13% with increasing numbers of oocytes. Stepwise logistic regression ($P < 0.001$) identified three cut-points (4, 10, and 15 oocytes) at or beyond which the probability of clinical miscarriage fell. It failed to find any oocyte number above which the miscarriage rate rose again. The miscarriage rates were 20.0% (1–3 oocytes), 15.5% (4–9 oocytes), 13.8% (10–14 oocytes) and 13.1% (≥ 15 oocytes). After adjusting for female age, the effect of oocyte numbers on the clinical miscarriage rate was reduced, but not eliminated.

These findings conclude that poor responders have a higher clinical miscarriage indicating that poor ovarian response is associated with a parallel decline in both oocyte quantity and quality (Sunkara et al., 2014).

Though decline in the LBR (live birth rate) observed with higher number of eggs could be due to the deleterious effect of the raised serum E2 levels affecting at the level of embryo implantation (Valbuena et al., 2001; Mitwally et al., 2006; Joo et al., 2010) but not beyond that.

Ji et al. (2013) concluded that the fresh embryo LBR per started cycle increased with the number of retrieved oocytes up to Groups 2 and 3 (6–10 and 11–15 oocytes) and then (> 15 oocytes) decreased, because of the high number of cycles with all embryos being cryopreserved, in order to avoid moderate—severe OHSS in group 4 (> 15 oocytes). However, the cumulative LBR per started cycle continued to increase with oocyte number, as did the incidence of moderate—severe OHSS. There was no significant difference in the miscarriage rates among the patient groups.

3. *Frozen embryo transfer (FET):*

There is no difference of miscarriage rates between fresh and FET, though FET resulted in an increase in the clinical pregnancy rate (RR 1.31; 95% CI 1.10–1.56) and the ongoing pregnancy rate (RR 1.32; 95% CI 1.10–1.59) (Evans et al., 2014). But, on comparing different FET protocols, a higher miscarriage rate was observed in the HRT (hormone replacement therapy) group when compared to hCG or LH surge (21.2% vs. 12.9% vs. 11.1%, $P < 0.01$) (Cerrillo et al., 2017).

4. *Cryopreservation technique:*

Earlier, slow freezing technique was used to cryopreserve gametes/embryos. Recently vitrification technique has replaced this due to better results. According to Kaartinen et al. (2016), the clinical pregnancy and delivery rates were similar for both freezing methods. The clinical miscarriage rate in the slow-freezing group was higher (29% vs. 15.7%). Slow freezing and thawing has been detected to induce numerical chromosomal changes in human embryos, which could be explained by increased ice crystal formation. The embryo DNA integrity index was higher in vitrified than in slow-frozen blastocysts which could explain the lower miscarriage rate.

5. *Multiple pregnancy:*

More than one embryo is very often transferred in an IVF—ICSI cycle to improve the pregnancy rate. This leads to a higher incidence of twins, triplets and sometimes even high order multiple pregnancies.

According to Sullivan et al. (2013), the number of embryos transferred per ART cycle varied among countries. The average number of embryos transferred overall has decreased from 2.47 in 2002 to 2.35 in 2004 reflecting increase in single and double embryo transfers from 67.6% in 2002 to 73.2% in 2004. Positively, triple and quadruple embryo transfers decreased between 2002 and 2004 from 28.6% to 25.1% and 13.7% to 11.6%, respectively, and this has contributed to the decline in the trend of multiple deliveries following ART.

The lowest proportion of ≥ 4 fresh embryo transfers were reported from Australia/New Zealand at 0.4% then Europe at 3.3% and the highest from Asia at 42.5% with the Nordic countries reporting no embryo transfer cycles of ≥ 4 . The proportion of single embryo transfers (SETs) increased from with the highest reported by Sweden (67.4%), Belgium (48.9%) and then Finland (47.0%).

The proportion of twin deliveries marginally increased from 24.8% in 2003 to 25.1%, while the proportion of triplet deliveries continued to decrease, from 2.0% to 1.8%. However, these rates differed largely among countries; the percentage of twin births ranged from 5.6% in Sweden to 48.2% in Peru, and births of triplet and higher order multiples from, 1% in several countries (including Sweden, Belgium, Australia, New Zealand, Norway, Denmark, and France) to 10% in Lithuania and six Latin American countries (Argentina, Brazil, Ecuador, Guatemala, Mexico, and Venezuela).

Similar rates of multiple deliveries were seen for FET in 2003 and 2004, with twins at 17.0% and triplets or higher at 1.0%. The percentage of transfers with four or more embryos in fresh cycles increased slightly, to 11.6% from 10.8% in 2003.

According to Tummers et al. (2003), the overall incidence of spontaneous abortion—in twin pregnancies was 17.1% (12.1% vanishing twins and 5.0% complete miscarriages) and in singleton pregnancies was 21.7%. The incidence of miscarriage in the twin pregnancies, expressed per gestational sac, was 11.1%. Once fetal heart activity was present, the risk of abortion (per

gestational sac) was 7.3%, which is significantly lower than that in singleton pregnancies. Twin pregnancies after IVF have a better potential for survival than singleton pregnancies.

According to La Sala et al. (2016), overall clinical miscarriages (odds ratio [OR] 4.9, 95% confidence interval [CI] 3.4, 6.9) and live births (OR 0.2, 95% CI 0.1, 0.3) were, respectively, higher and lower when compared to patients who had one clinical twin pregnancy. The overall risk of perinatal complications was significantly higher in patients who had one twin delivery rather than patients who had two consecutive singleton deliveries. Thus, he concluded that compared with two consecutive singleton pregnancies, twin pregnancies are characterized by higher success rates but worse perinatal outcomes irrespectively of vanishing twin syndrome. Thus, reducing the number of embryos transferred should be encouraged for better perinatal outcome.

6. ART laboratory parameters:

● Air quality:

Filtration units have been shown to reduce airborne concentrations of toxic volatile organic compounds (VOC), chemical contaminants and particles in IVF laboratories. Control of air pollution in ART laboratory, operating and transfer rooms through the construction of cleanrooms equipped with carbon-impregnated filters [like Class 100 (ISO 5; $n = 248$) cleanroom] for air and incubators results in better good quality embryo formation, cleavage and pregnancy rates, and in lower spontaneous abortion rates (Esteves et al., 2004).

● Culture media:

The pregnancy rate and implantation rate in the group without HEPES [4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid] were statistically significantly higher than in the control group where media buffered with HEPES used. But no differences were observed for the number of embryos transferred, top-quality embryo rate transferred, or abortion rate between the two groups (Morgia et al., 2006).

● ICSI (intra-cytoplasmic sperm injection):

ICSI is suspected to increase the chromosomal aberrations as it bypasses natural selection mechanisms and may increase first trimester aneuploidy rates (Kim et al., 2010). Explanations for this include (i) physical or biochemical disturbances of the ooplasm or meiotic spindle, (ii) injection of biochemical contaminants, (iii) injection of sperm associated exogenous DNA, (iv) injection of sperm carrying a chromosomal anomaly, (v) transmission of genetic defects that may be related to the underlying male-factor infertility, (vi) male gametes with structural defects, (vii) anomalies of sperm activating factors, (viii) potential for incorporating sperm mitochondrial DNA, and (ix) female gamete anomalies.

Kim et al. (2010) concluded that out of total miscarriages, 52.62% were found to be cytogenetically abnormal among all patients, but no statistical difference was found between ICSI and conventional IVF group (54.3% v/s 55.3%, P 0.503).

General causes miscarriage

Many causes of abortion not specifically related to ART but can cause abortion in any pregnancy conceived naturally or through IUI or ART.

1. Chromosomal abnormalities (Agenor and Bhattacharya, 2015):

Almost 50% of early pregnancy losses take place due to chromosomal abnormalities, mostly aneuploidy. These maybe genetic, but more often than not, they arise de novo, due to aberrations in chromosomal structure during development.

- (a) *Trisomies*: Seen most often in cases of advanced maternal age (≥ 35 years), trisomy 21, 16, and 18 are known to be a cause of early pregnancy loss.
- (b) *Y-chromosome abnormalities*: Translocation in the Y-chromosome is commonly detected, leading to defective spermatogenesis.
- (c) *Factor V Leiden*: This mutation is genetically inherited, predisposing the affected individual to thrombosis.

Pre-implantation genetic screening (PGS) can be offered to rule out chromosomal aneuploidies in embryos before transfer.

2. *Antiphospholipid antibodies*: especially anticardiolipin antibodies and lupus anticoagulant have been linked with pregnancy loss, right from the implantation stage, through to late preterm labor. These antibodies are said to impair trophoblastic invasion of spiral arterioles, reducing the blood supply to the fetus, causing improper placental development, PIH and changes in fetal blood flow patterns. Aspirin and low molecular weight heparin are commonly used treatment option.
3. *Anatomical defects in the uterus*: These maybe both congenital and acquired. Defects like uterine septum, unicornuate uterus, distorted anatomy due to endometriosis, uterine fibroids, polyps and intrauterine synechiae all can cause pregnancy losses, especially 2nd trimester loss. Surgical correction, when appropriate helps to reduce the risk.
4. *Cervical incompetence*: Cervical incompetence, often undiagnosed until it is too late, is a common cause of recurrent and preventable mid-trimester pregnancy loss. Cervical cerclage is performed in second trimester to prevent such losses.
5. *Endocrine cause*: The main causes include poorly controlled diabetes, overt hyperthyroidism and hypothyroidism, hyperprolactinemia and luteal phase defect.
6. *Infections*: Infections can cause sporadic losses, never recurrent. The organisms responsible are Chlamydia, ureaplasma, mycoplasma, and toxoplasma.
7. *Environmental cause* (Gardella and Hill, 2000): Heavy metals such as mercury and lead, alcohol, organic solvents, and ionizing irradiation are confirmed teratogens which on exposure can lead to miscarriage. The suspected teratogens are caffeine (> 300 mg/day), and cigarette smoking, whereas the teratogenic potential of pesticides remains unknown.
8. *Maternal obesity* (Lashen et al., 2004): Obesity is associated with increased risk of first trimester and recurrent miscarriage. Weight loss should be encouraged for obese patients before ART (Sim et al., 2014).

9. Immunological factors (Agenor and Bhattacharya, 2015):

- (a) *HLA antigens*: HLA expression influences various stages of gestation. Its expression is associated with increased chances of an embryo implanting successfully as well as elevated embryo cleavage rates.
- (b) *Antisperm antibodies*: although these are mainly said to cause infertility, their role in miscarriages has also been studied, leading to lower pregnancy rates.
- (c) *Integrins*: these are adhesion molecules that facilitate cell to cell interactions, and are considered essential for the binding of a sperm to an oocyte. They are also essential for the process of implantation and later on for placental development. Lack of integrin expression can lead to miscarriages.
- (d) *LIF*: leukemia inhibitory factor is required in the endometrium to facilitate the process of implantation. Its absence or reduction has been linked to human reproductive failure.
- (e) *Cytokines*: Cytokines are involved in gamete development, trophoblast invasion, implantation, placental development, decidualization and immune tolerance to pregnancy.

Th1 cytokines are said to be cytotoxic, causing tissue injury, whereas Th2 cytokines promote antibody production and cell healing. Thus when the Th1:Th2 balance is disturbed in favor of the cytotoxic cytokines, pregnancy is affected.

- (f) *Natural killer cells*: increased NK cell activity, especially the uterine NK cells, as compared to the peripheral NK cells, has been implicated in impaired placental development leading to reproductive failure.
- (g) *Haemostatic pathways*: Proteins C, protein S, factor V Leiden, homocysteine, are some of the factors that have been considered responsible for pregnancy loss.

Management strategies are vast and detailed. In a nutshell, they involve detecting the underlying cause first, and then solving it to be able to take a pregnancy to term.

Introduction

Monitoring national and regional trends in utilization as well as safety and effectiveness of assisted reproductive technologies (ART) treatments constitutes an important task. Data generated systematically, incorporating heterogeneity in populations but large numbers of cases, have limitations. However, they can often serve as external quality control to be used by institutions performing ART in a given region, and also to compare themselves with different regions of the world. Additionally, monitoring trends in effectiveness and safety contributes to developing better health interventions and appropriate public policies. From a consumer/patient perspective, having access to a large number of cases helps empower infertile couples in their capacity to evaluate risks and benefits when requesting in vitro fertilization (IVF). It is often difficult for an infertile and sometimes vulnerable person to understand and to weigh the risks and benefits of offered treatments. Access to an objective and external database is often well received by infertile persons when deciding if and which treatment option should be undertaken, for example how many embryos to transfer, whether preimplantation genetic testing (PGT) should be undertaken, or even whether treatment should be undertaken at all.

Types of Art Registries

Registries can be *voluntary*, as in all Latin America, Asia and the Middle East or *obligatory* and therefore enforced by law or by other regulatory bodies. Such is the case in the United States, Australia, the United Kingdom, France, Belgium, and the Nordic countries. The major difference between these two systems is that when reporting is obligatory, national data include all or the vast majority of centers offering ART services; while in cases with voluntary registration, data reported are most of the time incomplete. There are exceptions such as Chile and Uruguay in Latin America; and also in larger populations such as Japan, where in spite of a non-obligatory reporting system, the majority of centers send their data to a centralized organization. Another characteristic seen exclusively in obligatory reporting systems is the possibility to publicly disclose the results from each participating institution, as it is in the United States.

Countries can also report their data through *national registries*, as in most European countries, United States, Australia and Japan; or via *regional registries* such as in Latin America and Africa. In these two continents, most countries report their national data, with information provided by a regional organization, such as REDLARA (www.redlara.com) for Latin America and ANARA (www.anara-africa.com) for Africa. The reason for this triangulation of data collection and data reporting has to do with difficulties encountered by many institutions to disclose their results to a potentially competing institution. Irrespective of how ART data are collected, it is very useful for countries to have access to their own data in order to generate evidence-based public policies and compare their practices and outcomes with other countries or regions.

From another perspective, registries can collect *cycle-based or individualized data*, also called case-by-case registry; this has the advantage that every individual treatment cycle can be followed from the start of stimulation or cycle monitoring until birth or miscarriage. This is the case in most European countries, Australia, US and Japan; and since 2010 in Latin America when the registry became the only regional registry with a cycle-based reporting system, which now includes 15 countries in the region. Today, South Africa is also reporting with individualized data collection; this system is now being expanded to other African countries through the African Network and Registry for Assisted Reproductive Technology (ANARA).

Another way of collecting ART data is through summary collection in which different treatment modalities are grouped into age groups, number of embryos transferred, fertilization technique, etc. In this case, very useful information is still collected but there are several limitations when interpreting data. For example, it is not possible to calculate cumulative events, such as the cumulative delivery rate of women age 37. In summary, registries you can add the number of deliveries of fresh transfers plus frozen embryo transfers (FET) of all women age 37–39 but it will not be possible to extrapolate the cumulative birth rate that a woman of a certain age has after transferring all the embryos that were generated and transferred during her fresh plus frozen transfers. Another big advantage of a cycle based registry is the possibility to associate birth outcome such as gestational age at delivery, weight of newborns, and malformation rate to any preceding event, for example type of stimulation protocol or whether embryo transfer (ET) was performed fresh during the stimulation cycle or delayed for a frozen–thaw cycle.

World Art Registry

The International Committee for Monitoring Assisted Reproductive Technology (ICMART) is the only registry reporting global data by country and region. This committee started as the International Working Group of Registers in Assisted Reproduction, generating the first world reports of procedures performed in 1989 (Lancaster, 1996); and later reorganized as ICMART. The data corresponding to ART treatment cycles performed every year are collected from five regional ART registries, compiled from national registry data in the case of Europe and North America, and from individual ART clinics gathered together in a regional registry in Latin America, Australia/New Zealand, and intermittently in the Middle East. Also, data are collected from national registries directly reporting to ICMART in several Asian countries such as Japan, India, Taiwan, Korea, and Vietnam; as well as in South Africa and Israel. Irrespective as to whether the national registry gathers information on a cycle based modality or in a summary modality, ICMART data collection and reporting system uses a summary modality.

The ICMART data collection uses forms describing the organization of each country's register, the practice of ART in terms of utilization, and the results of IVF, intracytoplasmic sperm injection (ICSI), and frozen embryo transfer (FET), and includes initiated cycles, follicular aspirations, ETs, clinical pregnancies, deliveries, and newborns. Whenever available, these variables are further classified according to the fertilization technique, woman's age, number of embryos transferred, and gestational age at delivery. Other forms describe pre implantation genetic testing (PGT), oocyte donation (OD), immediate complications for women, and congenital anomalies detected during the perinatal period. The ICMART forms for data collection can be found at www.icmartivf.org.

One of the major requirements for a global and systematic recording of reproductive health data is to have a common language. ICMART has been a leader in developing infertility glossaries, first to allow for standard registration of ART data, and most recently in partnership with numerous other international organizations, The International Glossary on Infertility and Fertility Care, 2017 has been developed and published (Zegers-Hochschild et al., 2017a,b). This serves as a basis for systematic recording of data and, among other advantages, a standard way of reporting outcomes.

Art From a Global Perspective

Utilization is Affected by Availability and Access

The global number of clinics reporting to ICMART has grown significantly. In the year 2000, 1400 clinics in 49 countries reported approximately 460,000 initiated cycles with an estimated 178,000 babies born (Adamson et al., 2006). In 2012, ART procedures were reported by 2551 clinics in 69 countries. The actual number of initiated cycles reported was 1,559,982, with an estimate above 1,700,000, and approximately 400,000 babies born (de Mouzon et al., 2012). This represents almost a 2.5 fold increase in these 12 years. Europe continues to perform the largest number of procedures, representing 47%, followed by Asia with 30% and North America with 12% (Fig. 1A). Furthermore, the number of babies born follows a similar pattern. Of an estimated 400,000 babies born in 2012, Europe contributes 45.2% followed by North America with 21.7% and Asia with 19.2% (Fig. 1B).

The higher proportion of births in North America compared with Asia results from, among other factors, a higher delivery rate (DR) per initiated cycle in the United States, as well as a higher proportion of multiple births. Although ART services are available in almost every country in the world, the majority of countries have access restricted to those who can afford out of pocket funding; an exception is countries where infertility treatment is provided free of cost or reimbursed. A description of how each country deals with fertility treatments can be found in an infertility survey published regularly by the International Federation of Fertility Societies (IFFS) (Surveillance, 2016). The number of ART procedures per million inhabitants (utilization) represents a measure of access. As seen in Fig. 2, countries with facilitated access to ART perform approximately 2500 cycles per million inhabitants compared with only hundreds in poorer countries with out of pocket funding. The major driver of utilization is affordability (Chambers et al., 2014).

Effectiveness

The effectiveness of ART treatments can be expressed in different ways. The clinical biomarker most frequently used is the clinical pregnancy rate (CPR); and although this is not a robust marker, it is widely used because infertility is defined as "the failure to achieve a clinical pregnancy"; therefore, pregnancy becomes the first successful step in an infertility treatment, irrespective of whether pregnancy is followed by miscarriage or the delivery of a healthy live birth. A more accurate marker is the delivery rate (DR) per initiated, aspirated or transferred cycle. There is overall agreement that the most accepted measure of success is the birth of a healthy singleton. However, when balance is placed between the birth of twins against the absence of pregnancy, twins is almost always considered a blessing—especially because most couples have limited chances in their lifetime, mainly due to cost, stress of treatment and age.

World trends in effectiveness over a 12-year interval

Between the year 2000 and 2012, the CPR and DR/aspiration have remained almost unaltered. At first this seems disappointing, considering major improvements in drugs for ovarian stimulation (OS), laboratory facilities and clinical knowledge. However, these small changes in CPR and DR are coupled with a significant drop in the average number of embryos transferred, from 2.6 embryos

Fig. 1 (A) Regional contribution to ART initiated cycles performed worldwide in 2012. (B) Proportion of babies born from ART treatments by region in 2012.

in 2000 to 1.88 in 2012 (**Table 1**). This resulted in a significant reduction in the proportion of twins and, especially ≥ 3 babies, from 2.8% of births in 2000 to $< 1\%$ in 2012. Therefore, the major improvement in ART in this 12 years interval has been towards a better balance between effectiveness and safety.

Cumulative/Total delivery rate as the ultimate marker of effectiveness

Cumulative and total delivery rates or live birth rates ([Zegers-Hochschild et al., 2017a,b](#)) on a global basis are difficult to document since most countries report aggregate data to their own registries and then to ICMART, rather than cycle-based data. Despite this, estimated cumulative delivery rates can be extrapolated by adding all fresh plus FET cycles in women at certain age categories; this is

Fig. 2 Availability of ART treatments in a selected number of countries, expressed as number of cycles per million total population.

Table 1 Clinical pregnancy rate and delivery rate per aspiration in IVF/ICSI by year (2000, 2005, 2008, 2010, 2012)

Year	$\bar{X}$ ET	Procedure	CPR/Asp	DR/Asp
2000	2,6	CII (IVF)	26,7	18,6
		ICSI	27,7	20,4
2005	2,29	CII	29,8	20,3
		ICSI	28,9	19,2
2008	2,1	CII	26,1	19,1
		ICSI	28,7	18,9
2010	1,9	CII	25,4	19,1
		ICSI	26,8	20,0
2012	1,88	CII	24,4	17,7
		ICSI	24,9	17,9

$\bar{X}$ ET = mean of embryos transferred.

CPR/Asp = clinical pregnancy rate per aspiration.

DR/Asp = delivery rate per aspiration.

how it is done in the world reports published by ICMART (Dyer et al., 2016). It is important to note that cumulative delivery rates resulting from fresh plus frozen transfers have greater impact in younger women compared to women >40 and is also strongly affected by the number of oocytes collected in the fresh cycle (Toftagert et al., 2017). For example, data provided by the Latin American registry show that in women <35 delivery rates increase from 29.2% in fresh transfers to a 41.3% cumulative delivery rate when FET cycles are added. However, in women of 40–42 years, the increase is only from 14.5% to 17.6%, having much less clinical impact (Zegers-Hochschild et al., 2014). Similar results for cumulative live birth (CLBR) were recently reported in a large population extracted from the national registry of the United Kingdom. While CLBR in young women could reach up to 40%–67%, in women age 40 years or more the increment in CLBR was only from 5.9% to 9.8% (McLernon et al., 2016).

Reaching global consensus on how to calculate CLBR will be important in the future to enable the comparison of effectiveness within and across registries. Global markers of reproductive outcome must be understood as references to examine similarities and differences. It is only by carefully collecting, collating and analyzing country specific variables that one can really determine factors that influence the way ART is practiced and the outcomes obtained.

Safety

Issues of safety primarily concern multiple birth and ovarian hyperstimulation syndrome (OHSS). OHSS has only recently been monitored and reported globally; furthermore, lack of standardized definition of reportable occurrence has made interpretation of incidence difficult. However, increasing attention to prevention and documentation is occurring globally and data are being collected to follow its incidence more closely.

Lowering multiple births as a safety component has been progressively incorporated into ART management, but important differences persist among countries. The range of twin and triplet deliveries for 2012 was from 11% to 0.4%. Variations among

regions are shown in Fig. 3. Australia, Asia, and Europe have the lowest number of embryos transferred and, consequently, the lowest rate of multiple births. Globally, countries with the lowest proportion of twins and triplets are Japan with 3.9% twins and 0.1% triplets, followed by Sweden with 5.6% and 0.1% and Australia with 6.3% and 0.1%, respectively. The opposite extreme is also found in Europe where Serbia and Lithuania have 36.6% and 32.3% of twins respectively. The USA report 26.4% twins and 1.0% triplets while in Latin America, Argentina has the lowest rate of multiples, with 16.9% twins and 1.0% triplets, while Guatemala and Nicaragua report 31.6% and 41.9% twins, respectively, but reporting very few pregnancies.

The proportion of twins and triplets or more are a direct consequence of the number of embryos transferred. Fig. 4 shows the proportion of single, double and triple or more embryo transfers (SET, DET and TET, respectively) in countries mentioned above. There is a direct correlation between the number of embryos transferred and multiple pregnancy. Furthermore, there is a direct correlation between multiple gestation and perinatal mortality which, according to the Latin American registry (Zegers-Hochschild et al., 2014), increases from 23 to 35 per thousand from singletons to twins.

Multiple births not only result in poorer outcomes for mothers and babies but in greater long-term costs associated with caring for complicated pregnancies and preterm birth—a cost and responsibility that in high resourced countries is commonly taken care

Fig. 3 Regional variation in the proportion of multiple births (twins and triplets or more) and its relationship with the mean number of embryos transferred. The proportion of triplets and a more can be affected by embryo reduction which is practiced in few regions in the world.

Fig. 4 Country variability in the proportion of single embryo transfer (SET), double embryo transfer (DET) and triple or more embryos transferred. There are big differences within regions, such as Sweden and Germany in Europe, or Argentina and Mexico in Latin America.

of by society through government health plans (Adamson et al., 2006); however, in less well-resourced countries multiple births usually create major financial burdens for affected patients and their households. This provides a strong argument for the development of public policies in which individuals and society as a whole share the costs and responsibilities that result from fertility treatments.

Improving The Data in Registries

Original data collection for registries was very rudimentary, consisting of written reports that were collected, collated and analyzed by hand with calculators. Subsequently, computers and computer programs have improved our ability to capture, collate and analyze data in a much more sophisticated fashion. Currently, progress is enabling electronic, cloud-based ART data collection and transfer of data electronically from one registry to another; this facilitates the development of combined databases.

The use of standardized definitions that are the same globally have continued to improve registry data. The most recent is The International Glossary on Infertility and Fertility Care, 2017 (Zegers-Hochschild et al., 2017a).

One of the most important aspects of obtaining good data is to have prospective reporting of cycles. This means that all ART cycles are entered at the time there is an intention to treat the patient: with fresh transfer ART cycles this is date on which ovarian stimulation is started; with frozen-thaw cycles this is the date on which medications are given to establish a “controlled” cycle or at which cycle monitoring is started in preparation for a frozen/thaw transfer in a natural cycle. With prospective reporting, all intended treatment cycles are counted, including those which may be canceled later for various reasons. This is critical if we are to know the “real world” experience of patients and the true “success” of ART. It also limits “cherry picking” of patients in which only those who respond well to ovarian stimulation medications are counted in ART results. This results in reported outcomes that appear better than that actually experienced by patients.

One of the advantages of electronic data collection is that software programs can be written into the data collection system to ensure accuracy, consistency and completeness of the data that are reported in different areas of the registry; this also reduces simple arithmetical errors.

Additionally, data verification programs can check for both expected and unexpected problems where the reported results do not make sense mathematically or biologically. These data can then be double checked at their source to ensure that accurate data are included in the registry.

Finally, electronic data collection can be used to run software programs to identify reporting entities that have outliers in terms of patient treatment or outcomes, for example, high multiple birth rates or very low miscarriage rates. This information can be used to assess programs needing attention with respect to quality of care and/or integrity of their data. Any outliers must be assessed by knowledgeable clinicians and scientists objectively, almost always in conjunction with the originator of the data, usually an ART clinic, but sometimes even a nation state.

Electronic data collection can be used to screen the data provided, and to identify those entities that might require on-site visits or more in-depth assistance to ensure quality data are submitted by that entity.

The Influence of New Technologies on Registries

Data collection is influenced by changes in technology. For example, with the increasing use of day 5/6 blastocyst embryo transfer, implantation rates improved because of the biologically-based higher implantation rates of blastocysts over cleavage stage embryos. Therefore, it is important for registries to report on whether embryo transfers are performed on day 3 or day 5 because this creates significant differences in pregnancy rates.

Intracytoplasmic sperm injection (ICSI) treats male factor infertility exceptionally well, but is not necessary when sperm function normally. Overall, live birth rates are probably slightly less with ICSI and birth abnormalities are slightly higher, so it is important to know the proportion of cycles that involve ICSI. This ranges from just over 50% in some countries to almost 100% in others.

Elective single embryo transfer (eSET) has been increasingly promoted over the past two decades in order to decrease multiple pregnancy rates; however, it is associated with lower pregnancy rates on the initial transfer of the embryo, although not lower cumulative pregnancy rates. Since different ART clinics and different countries and regions have incorporated eSET at different rates, there are very different proportions of patients treated with eSET or double embryo transfer (DET) or even higher number of embryos transferred. It is essential to know the proportion of eSET and average number of embryos transferred in order to interpret pregnancy rates.

Cryopreservation affects all aspects of ART. This impact has increased significantly with the advances in vitrification and markedly improved embryo and egg viability and increased pregnancy rates: eSET is performed more often; more embryos are cryopreserved; more cycles are frozen as opposed to fresh embryo transfer cycles; cycles are not canceled for ovarian hyperstimulation syndrome (OHSS) as often; more cycles are “freeze all” cycles because of high progesterone levels or less than optimal endometrium; more PGT is performed; more fertility preservation both of embryos and eggs is performed. All these changes in clinical protocols change the proportions of types of cycles and the pregnancy rates associated with them. Registry data can only be interpreted with an understanding of these technology and clinical protocol changes.

Freeze all cycles have created a special difficulty for interpreting registry data. Historically, the outcome of a cycle was relatively simple to report—stimulation drugs were given, eggs retrieved, embryos created and at least one replaced within a few days. Outcome was pregnancy or live birth per cycle start, egg retrieval or embryo transfer. However, with freeze all cycles there is no transfer, so the pregnancy rate is zero for a fresh transfer. Yet the first frozen/thaw transfer cycle will use, statistically, a better embryo than in a patient who already had the best embryo selected for the fresh transfer. If the transfer does not occur in the same year as the retrieval, this creates the need to report a cycle outcome in the year following the ovarian stimulation (cycle start/intended treatment) and the egg retrieval, markedly increasing the complexity of reporting. This problem is compounded when eggs or embryos are cryopreserved for fertility preservation and may not be used for several years (egg or embryo banking). Complex and standardized rules for linking the retrievals with the transfers in reporting such cycles need to be implemented by registries to deal with these issues so that the numbers reported in different registries are based on the same calculations. On a global basis, these complex issues are just beginning to be addressed.

PGT has also changed registries because essentially all cycles are cultured to blastocyst rather than just cleavage stage, generally all the embryos are cryopreserved for later use, and there is selection of embryos so that a higher quality embryo is chosen for transfer. However, PGT does not increase the reproductive capacity of the embryos created from a single transfer—rather, the cumulative pregnancy rate from all the embryos is reduced because of loss of reproductive potential from embryo biopsy, testing errors, harm from cryopreservation and mosaicism. These factors must be considered when interpreting the data in a registry.

Summary

Registry data collection is essential for our professional understanding of ART practice and to inform patients and policy makers. It is much more complex than many appreciate. For years registries were overlooked as an integral component of quality control for all stakeholders in ART. However, the importance of global ART reporting is now recognized. Fortunately, much improvement has occurred in the amount and quality of data collected and reported. However, many challenges remain. Ongoing commitment to improved data collection for ART registries is necessary so that we can continuously improve access, utilization, effectiveness and safety of ART.

Glossary

Feto-fetal transfusion syndrome (FFTS) FFTS is a complication of disproportionate blood supply. One baby will receive too much blood and the other will receive too little.

Gonadotropin Human gonadotropins are glycoprotein hormones secreted by anterior pituitary of brain (FSH and LH) or placenta (HCG) that work to regulate sexual development, sex hormone secretion, and reproductive function.

Gonadotropin-releasing hormone (GnRH) Peptides synthesized and secreted by hypothalamus to regulate the release of Gonadotropins.

Intrahepatic cholestasis of pregnancy (ICP) ICP is a medical condition in which cholestasis (bile cannot flow from the liver to the duodenum) occurs during pregnancy. It typically presents with intense itching, usually on the hands and feet.

Preeclampsia Preeclampsia is a disorder of pregnancy characterized by high blood pressure and signs of damage to another organ system, most often the liver and kidneys.

Premature rupture of the membranes (PROM) PROM is defined as rupture of membranes before the onset of labor.

Vascular anastomoses A connection between two or more blood vessels that are diverging or branching.

Zona pellucida A protective glycoprotein layer surrounding the oocytes in mammals.

Development of Multiple Pregnancies

The term “multiple births” refers to the delivery of two or more offspring from one pregnancy. Multiple births occur in almost all mammals and could be more common than singleton births in polytocous species. In contrast, multifetal pregnancies in low-ovulating mammalian species, such as cattle and primates, are often related with birth difficulties and health problems for both mother and newborns. This article will focus on human multiple pregnancies.

A multiple pregnancy may be the result of fertilization of more than one egg, or the division of a fertilized egg into identical fetuses, or a combination of both events. For example, twin fetuses can result from the fertilization of two separate ova, or the division of one fertilized ovum, referred to as dizygotic (fraternal) twins and monozygotic (identical) twins, respectively. Either or both processes may be involved in higher-order multiple pregnancies. There are various types of monozygous twins, depending on the timing of division. If the cleavage occurs within the first 72 h after fertilization, two distinct amnions and chorions develop. And this is termed as a dichorionic, diamnionic twin. In this case, either two placentas or a fused one develop. If zygotic splitting occurs during the blastocyst stage (between the fourth and eighth day of fertilization), twins share a placenta and chorion but have a separate amniotic sac, which is a monochorionic, diamnionic pregnancy. This type accounts for approximately 70% of all monozygous pregnancies. Least frequently, the zygotes split after the ninth day of fertilization when the amniotic sac is already differentiated, a monochorionic, monoamnionic twin pregnancy evolves. Incomplete division of zygotes after 13 days of embryogenesis results in conjoined twins. The development of monozygotic twins is shown in [Fig. 1](#).

The incidence of multiple pregnancies also varies with ethnicity, parity, heredity (predominantly maternal side) and nutritional factors ([Cunningham et al., 2014](#); [Luke and Brown, 2008](#)), whereas the frequency of monozygotic twin births is relatively constant worldwide.

The drastic surge in twinning rates over the past decades is largely attributable to the increasing use of infertility treatment, including drug-induced ovulation and in vitro fertilization (IVF), wherein more than one embryo is transferred into the uterus. It is estimated 30%–50% of multifetal pregnancies are conceived by assisted reproductive technology (ART) and about 35% of ART pregnancies are multiples ([Blondel and Kaminski, 2002](#); [Zhu et al., 2016](#)). In addition, monozygotic twinings are more commonly seen following ART procedures, as embryos are particularly susceptible to minor turbulences. Ovarian stimulation, zona pellucida manipulation, temperature fluctuations, blastocyst transfer, and prolonged embryos culture in vitro have been proposed as mechanisms contributing to the increased incidence of ART-associated monozygotic twins ([Aston et al., 2008](#)).

Deferred childbearing is another well-known risk factor for multiple pregnancies, independent of the application of ART ([Blondel and Kaminski, 2002](#); [Luke and Brown, 2008](#)). Women over 35 years of age are more likely to release more than one egg in a single menstrual cycle than younger counterparts. In general, there is an age-related fertility decline in both men and women, so the need of infertility treatment increases. Furthermore, older maternal age requires more aggressive therapies to achieve a pregnancy, which includes transferring more embryos.

Fig. 1 Development of monozygotic twins. Cunningham, F. G., Leveno, K.J., Bloom, S.L., Spong, C.Y., Dashe, J.S., Hoffman, B.L., Sheffield, J.S. 2014. *Williams obstetrics*, 24th edn. McGraw-Hill Education, New York.

Maternal Adaptations to Multiple Gestations

Systemic physiologic changes take place to meet the needs of pregnancy. Although the nature of most adaptive changes is quite similar in multiple and singleton pregnancies, multiple pregnancies are featured with more hyper dynamic circulation as the maternal body is at even higher demands of support (blood, oxygen, and nutrition supply, and clearance of fetal waste) and protection.

Nausea and vomiting of pregnancy is more commonly seen in women carrying multiple fetuses because of comparatively higher serum hCG levels. Initiated by hormonal change, the blood volume expansion following sodium and water retention is also more significant in women with multiple fetuses.

In a typical singleton gestation, maternal diastolic blood pressure continues to drop until mid-pregnancy in response to the decrease in peripheral vessel resistance but will gradually recover to nonpregnant level by term, while systolic pressure is less affected (Norwitz et al., 2005). During multifetal pregnancies, however, a greater fall in diastolic pressure is observed as early as 8th week, along with a higher rise at term (Cunningham et al., 2014; Norwitz et al., 2005). Marked augment in cardiac output achieved by a greater increase in heart rate and stroke volume during multiple gestation serves to maintain the blood pressure and thus the perfusion to fetoplacental unit throughout pregnancy.

The greater enlargement of uterus during multiple pregnancies exerts stronger space occupying effects on adjacent organs, especially in advancing pregnancy. Thus the magnitude of respective changes is exaggerated. Enlarging uterus compresses large blood vessels (venae cava inferior and aorta); consequently result in edema, supine hypotension, and regional anesthesia. Gastrointestinal functions are compromised as the stomach and intestines are appreciably displaced by the expanding uterus.

Alterations in respiratory system are initially induced by the change in hormones and later by the anatomical changes in thoracic cavity secondary to abdominal distention (Cunningham et al., 2014; Norwitz et al., 2005). Both the hyperventilation caused by

elevated progesterone and the rise of diaphragm is more significant with multiple pregnancies as compared with singletons (Norwitz et al., 2005), leading to a further reduction in residual volume and an increment in tidal volume. But mother-to-bes carrying multiples claim to experience more breatheless moments (possibly associated with the direct effect of progesterone and the abnormally decreased abdominal muscle tone).

Maternal Complications of Multiple Pregnancies

As per discussed, multiple gestations are associated with more profound body changes, which predispose mothers to almost all potential pregnancy and obstetric complications. The risk of anemia, pregnancy-induced hypertension, preeclampsia-eclampsia, postpartum hemorrhage (PPH), premature rupture of membrane, intrahepatic cholestasis of pregnancy (ICP), cervical incompetence, diabetes mellitus, placental insufficiency, and cesarean delivery were substantially increased in women with high-order multiple gestations (Cunningham et al., 2014; Norwitz et al., 2005; Wen et al., 2004). A dose-response relationship (risk goes up with gestational plurality) is observed in certain complications, such as pregnancy-associated hypertension, diabetes mellitus, and placental abruption (Wen et al., 2004).

Hypertension

Being the second leading cause of maternal death, gestational hypertension, and preeclampsia can be very ominous if not diagnosed earlier. Epidemiological studies have demonstrated that despite lower blood pressure measured in mid-pregnancy, pregnancy-associated hypertension complicates 40% of twin pregnancies, 2–3 times higher than that in singleton pregnancies (McMullan et al., 1984). Apart from that, hypertensive disorders with multifetal pregnancies are characterized by earlier incidence and severer outcomes.

Postpartum Hemorrhage

Researchers found a twofold-increased risk of PPH and severe PPH (blood loss > 500 mL or 1000 mL within the first 24 h after termination of pregnancy, respectively) in women who had multiple births. The over-distended uterus and enlarged placental attachment area place mothers at greater risk of postpartum hemorrhage.

Preterm Premature Rupture of the Membranes (pPROM)

About 10% multiple pregnancies are complicated by pPROM (Norwitz et al., 2005), which is possibly caused by the over distention and subsequent hyperirritability of uterus.

Family Stress

The psychological well-being of parents cannot be neglected. Although couples raising multiples generally reported greater enjoyment, mothers are more likely to experience emotional distress and some may require psychotherapy (Blondel and Kaminski, 2002). Apart from that, one thing that also weighs on multiple-birth families is the financial stress thereafter.

Fetal and Neonatal Complications of Multiple Births

Multiple births represent a higher risk in fetal and neonatal complications, which may have a long-term effect on the growth and development of newborns. Notably, chorionicity is of greater importance in predicting the prognosis of multiples than zygosity (Cunningham et al., 2014). The incidence of perinatal complications is similar between dizygotic and dichorionic monozygotic twins. Nevertheless, monochorionic multiples are far more prone to structural anomalies, cord entanglement, and selective growth restriction. This excess in risk is, at least in part, due to the vascular anastomoses within placenta, which could result in a potential hemodynamic imbalance under pathological conditions. What's more, this shared circulation accounts for some unique complications in monochorionic twins, namely, fetofetal transfusion syndrome (FFTS), twin reversed arterial perfusion (TRAP), and acute hemorrhage of the survivor after the death of their co-twin (single intrauterine fetal demise, IURD).

Spontaneous Pregnancy Loss

The prevalence of miscarriage (unexpected pregnancy losses at ≤ 20 weeks or with a fetal weight < 500 g) in multiple pregnancies is seven times as that in singletons (Cunningham et al., 2014). This is not necessarily a negative trend, as spontaneous multifetal reduction conferred benefits of extending the duration of pregnancy to 34 weeks or longer (Skiadas et al., 2011). Monochorial placentation and male fetuses are of higher risk of spontaneous pregnancy loss (Norwitz et al., 2005).

Preterm Birth

Preterm birth (born before 37 gestational weeks) is the most common complication of multiple gestations. In an earlier study conducted in the US, over 50% of twins and nearly all higher-order multiples are born premature (Martin et al., 2012). By contrast,

only approximately 10% singletons are premature (Blondel and Kaminski, 2002). The risk of prematurity grows correspondingly with the number of fetuses in the pregnancy, and the length of gestation contrariwise. Premature labor could be spontaneous, induced by PPROM, or medically indicated. The increasing application of indicated premature births in recent years explains the corresponding increased premature birth rate in many developed countries. However, the effectiveness of this intervention to reduce neonatal mortality and morbidity is controversial.

Premature births remain the leading cause of perinatal adverse outcomes, contributing over 75% to perinatal mortality and morbidity (Norwitz et al., 2005). It is reported that preterm multiples are more likely to have cerebral dysfunction than their peers, while other studies have shown that the clinical outcome of preterm infants seems only to correlate with gestational ages, regardless of the etiologies of preterm delivery and plurality.

Intrauterine Growth Restriction

Intrauterine growth restriction (previously known as intrauterine growth retardation, IUGR) in multiple gestations is a common occurrence. Compared with singletons, multiples are at notably increased risk of IUGR for intrinsic (fetal characteristics) and extrinsic (maternal conditions, umbilical abnormality, and placental insufficiency) reasons. In general, the degree of growth restriction increases with fetal number. Delayed growth is closely associated with fetal death, inhibited neurodevelopment, and chronic diseases later in life.

Selective IUGR (sIUGR) refers to the growth discordance among multiples. Although the etiological causes of sIUGR in dichorionic twins vary, discordancy in monochorionic twins is mainly due to the unequal distribution of blood supply and hence nutrients and oxygen.

Low Birth Weight

Low birth weight (<2500 g at birth) is a risk factor for infant mortality and morbidity. Multiples are more likely to be low birth weight than singleton pregnancies due to higher incidence of preterm delivery and restricted intrauterine fetal growth.

Induced Twins Versus Natural Twins

More adverse outcomes are observed in induced twins compared with spontaneous twins, but only of slight difference. Multiple pregnancies following ART procedures represent a higher risk of spontaneous reduction, umbilical cord anomalies, stillbirth, prematurity, and low birth weight than naturally conceived ones (Skiadas et al., 2011; Lambalk, 2001). In another research, ART twins group was observed to have a significantly increased incidence of postpartum hemorrhage and small for date infant compared with natural twins group (Zhu et al., 2016) (Tables 1 and 2). Yet, it is not clear whether the impaired obstetric and neonatal outcomes of iatrogenic twins are associated with the artificial manipulation throughout the fertilization process, or the parental intrinsic characteristics responsible for their subfertility, or a combination of both.

Preventions of Multiple Births

The causes of multiple pregnancies are mostly patients' clinical characters (maternal age and sex hormone levels), ovarian response (number and size of follicles), and treatment methods (initial and total dose of gonadotropins, duration of ovarian stimulation, and number of embryos transferred). Therefore, physicians and patients could take measures to prevent the occurrence and the subsequent adverse effects of multiple births.

Maternal Age

Generally speaking, older maternal age is one of the most significant risk factors for multiple pregnancies. Besides, an increased risk of almost all pregnancy complications is observed in mothers aged over 35 carrying multiples. This fact can be seen through the changing trend of the ASRM Practice Committee's (the first society that issued the guidelines for multiple pregnancy) recommend as well (Murray and Norman, 2014): In Jan. 1998, the ASRM Practice Committee recommended that women younger than 35 years old should have only three embryos transferred. Those with an average prognosis (patients over 40 who had multiple previous embryo transfers without success) could have up to five embryos transferred. In Nov. 1999, the committee modified their recommendations and stated that patients with good prognosis (age under 35) should have no more than two embryos transferred, those with an average prognosis (35–40 years old) could have three transferred, and those with below-average prognosis (age older than 40 years or previous difficulties that could be identified) could have four transferred. In Jul. 2006, the committee changed the number of embryos transferred for patients with favorable prognosis under 35 into only one. Through the developing trend of the committee's recommendations, we could see that strict limitations on the number of embryos transferred are required, individual treatment plan should be modified according to patients' own conditions such as age, etc.

Number of Embryos Transferred

The most effective strategy for reducing multiple pregnancy rates in IVF cycles is to reduce the number of embryos transferred. Researches have shown that a mandatory single embryo transfer (SET) could result in a dramatic decrease of multiple pregnancy rates.

Zhu, L., Zhang, Y., Liu, Y., Zhang, R., Wu, Y., Huang, Y., Zhang, D. 2016. Maternal and live-birth outcomes of pregnancies following assisted reproductive technology: A retrospective cohort study. *Scientific Reports*, 6(1).

The AFS Ethics Committee stated in 1994 that the number of embryos to be transferred should be limited to eliminate quadruplet pregnancy and keep the rate of triplets to 1%–2% of all pregnancies. This statement was made to account for the variability among patients and the variability of success in various programs (Murray and Norman, 2014).

However, SET could also cause a sharp decrease of pregnancy rates when embryo quality is poor. Thus, the selection of good quality embryos is critical in SET, and longer culture of embryos until day 5 is recommended whenever possible (Esinler et al., 2014). However, in some patients, day-5 embryo transfer (ET) is impossible due to some unfavorable factors, such as poor embryo quality. For these patients, day-3 ET is mandatory and day-3 double embryo transfer (DET) for the second cycle could be considered. DET for these patients could improve pregnancy rates. But one should not forget that the occurrence of multiple pregnancies is still a problem in DET cycles.

Besides, the eagerness to become pregnant among most patients, especially the aged ones, might lead them to downplay or ignore the risk of multiple pregnancies. Patients' willingness should of course be involved in making surgical plans. It's a dilemma for both doctors and patients to consider.

Mild Ovarian Stimulation

During the past 15 years, there has been a marked increase in the use of two treatments (used alone or in combination) for unexplained infertility: induction of ovulation induction, in which the ovaries are stimulated with exogenous gonadotropins to develop several dominant follicles, and intrauterine insemination (IUI), in which motile spermatozoa are suspended in culture medium and injected transcervically into the uterine cavity (Balasch, 2004). However, it shows a rising trend of gonadotropins usage, which would probably lead to the increment of multiple pregnancies. To prevent this, clomiphene citrate could be postulated as a treatment option, but its effects on women with unexplained infertility it not satisfying (Balasch, 2004).

Ovulation can be induced by a number of agents, including gonadotrophins, pulsatile gonadotrophin releasing hormone, aromatase inhibitors, and selective estrogen receptor modulators, commonly known as antioestrogens. Clomiphene citrate is the antiestrogen most commonly used for ovarian stimulation. Multiple pregnancy in clomiphene ovarian stimulation generally occurs because of multifollicular development. Preventing the need for ovarian stimulation will limit an individual multiple pregnancy risk. In controlled ovarian hyperstimulation and intrauterine insemination cycles, a protocol of 50 IU of recombinant FSH daily combined with the use of GnRH antagonists and a policy of strict cancellation based on echographic criteria are associated with a satisfactory pregnancy rate per initiated cycle and a low risk of high-order multiple pregnancies. Clinical workers could use ultrasound monitoring or serum monitoring to detect or prevent multiple ovulation.

A major criticism to the strategy of mild ovarian hyperstimulation is that it reduces the rate of conception, but this assumption should be supported by more prospective randomized studies.

Reduction of the Number of Fetuses

Selective termination of the fetuses has been used during multiple pregnancy treatment, but the acceptability of these options for the couple will depend on their social background and underlying beliefs. There is no available data from randomized trials to inform the risks and benefits of pregnancy reduction procedures for women with a multiple pregnancy so far (Dodd et al., 2015).

Introduction

There has been a rapid and constant increase in the number of reproductive medicine attempts. Indeed, since the birth of the first baby conceived by in vitro fertilization (IVF) almost 40 years ago (Louise Brown in 1978), more than 5 million children have been born by assisted reproductive technologies (ART) (Hyrapetian et al., 2014). They now comprise roughly 2%–3% of all births in Europe and United States. However, the safety of these techniques has not been fully demonstrated, especially in the long term. Most studies have investigated perinatal outcomes.

Metaanalyses have revealed an increased risk of birth defects in singleton and multiple ART deliveries compared with births following natural conception (Rimm et al., 2004; McDonald et al., 2005; Pandey et al., 2012; Wen et al., 2012; Hansen et al., 2013). The absolute risk of birth defects in ART children could reach around 6.5%–7% (Hansen et al., 2013).

However, there are currently few data about the long-term health and development of ART children. The difficulty is to provide a comprehensive summary of the data. Only a handful of studies were prospective and most presented methodological bias such as a small sample size, were uncontrolled or had an inappropriate control group, used subjective criteria or had incomplete reporting notably when the analysis covered a long period and others lacked adjustment for parameters which could affect the health and development of these infants (Fig. 1). Indeed, it is important to take into account parental characteristics (age, life-style,

Fig. 1 Factors impacting the follow-up of children born after ART.

socio-economic status, chronic disease, smoking habits) and all of the factors related to the pregnancy (parity, obstetrical disease and, term of delivery).

In addition, very long follow-up periods needed to identify health problems such as metabolic disorders and cancers and thus led inevitably to surveillance bias.

Moreover, even though the practice of transferring single embryos is increasing, multiple pregnancy rates are higher in the context of ART. It is therefore extremely important to investigate the risk of adverse outcomes in singleton pregnancies only (Fig. 1).

The potential increased risks in ART infants could be a consequence of the ART procedure or inherent to the infertility problems per se. In humans, it is quite challenging to distinguish the responsibility of each of these factors. In addition, as several individualized methods are used during an ART procedure, it is difficult to isolate the impact of each technique.

Long-Term Health Outcomes

Growth and Pubertal Development

Several cohort studies have examined the growth and weight patterns of ART-conceived children, and have revealed conflicting results. Indeed, even though a few studies have reported that IVF children were significantly taller (Pruksananonda, 2001; Miles et al., 2007), the majority stated no significant difference in the growth of ART-conceived children versus naturally conceived (NC) children.

A study which followed children up to 3 years old found similar growth and development in ART and NC children and in multiple and singleton pregnancies (Yeung et al., 2016). These results have been confirmed in assessments at 8 years old (Belva et al., 2007) and 12 years old (Basatemur et al., 2010). However, the rare longitudinal studies reported a lower weight and height for ART-infants aged less than 6 months old and a growth catch-up at 3 (Ceelen et al., 2009) or 4 years old (Woldringh et al., 2011). These studies remain difficult to conduct as it is challenging to eliminate all confounding factors known to be associated with impaired childhood growth. Indeed, most studies included children that were born prematurely, small for gestational age (SGA) or born following multiple pregnancies, which are frequently associated with ART.

Concerning pubertal development, Ceelen et al. (2008a,b) found an advanced bone age and increased DHEAS and LH concentrations in pubertal IVF singleton girls whereas the pubertal timing was comparable with that in controls born to subfertile parents. Sakka et al. also found the increased DHEAS concentrations but only in SGA children (Sakka et al., 2010). However, the menarche, genital development in males and pubic hair development in males and females were similar in singleton ICSI- and NC-children (Belva et al., 2012).

General Health and Surgery

As recently reviewed, conflicting findings were also reported on the general health of ART-children (Kettner et al., 2015). Indeed, some studies did not find an increased risk of childhood illnesses (Pinborg et al., 2003; Place and Englert, 2003; Bonduelle et al., 2004; Belva et al., 2007; Knoester et al., 2008; Beydoun et al., 2010) or the consumption of hospital services (Belva et al., 2007; Knoester et al., 2008) up to the age of 5 years old for ART-infants as compared with NC-children. However, Hansen et al. reported relevant differences regarding the incidence of childhood illnesses, and hospital admissions up to the age of 3 years (Hansen et al., 2008). Later, another team confirmed that IVF-conceived children had more hospitalizations, and for a longer duration, than NC-children (Koivurova et al., 2007). Concerning childhood surgery, two studies found equal incidences in children conceived by ART and in NC-children (Pinborg et al., 2003; Ludwig et al., 2009). Moreover, a study based on questionnaires completed by young adults found that they were healthy and without any increased susceptibility to chronic diseases (Beydoun et al., 2010). However, an increased risk of urogenital surgery was observed among boys conceived by ART (Ludwig et al., 2009) but this was not confirmed by Knoester et al. (2008).

Vascular and Metabolic Disorders

Several studies have reported subclinical but significant cardiovascular changes in ART children compared to controls. Systemic blood pressure levels were reportedly higher among children conceived by IVF or ICSI than among NC-infants (Belva et al., 2007; Ceelen et al., 2008a,b) even after adjustments for birth weight, gestational age and the height of the children (Ceelen et al., 2008a,b). Similar results were observed in a small case-controlled series of IVF-conceived children (Sakka et al., 2010). In contrast, Belva et al. did not detect any difference even for resting blood pressure or after mild psychological stress in a cohort of 150 ICSI-conceived children as compared to 147 controls (Belva et al., 2007).

However, the studies on systemic and pulmonary vascular functions revealed significant differences between ART- and NC-offspring. Indeed, Sherrer et al. reported a 25% smaller flow-mediated dilation of the brachial artery, a faster pulse wave velocity, and a thicker carotid intima-media in ART-conceived children than in controls. Similarly, pulmonary artery pressure at high altitude was significantly higher (+30%) in ART offspring (Scherrer et al., 2012). Other studies also reported suboptimal cardiac diastolic function in the IVF-ICSI group, especially under identical stressful conditions (Valenzuela-Alcaraz et al., 2013; Zhou et al., 2014; von Arx et al., 2015; Liu et al., 2015). All of these data suggest that ART children may have underlying endothelial dysfunction (Fig. 2).

Fig. 2 Overview of health in ART infants as compared to controls (naturally conceived infants). → No effect. ↘ Decreased, with odds ratio (OR), relative risk (RR) or weighted mean difference (WMD). ↗ Increased, with odds ratio (OR), relative risk (RR) or weighted mean difference (WMD). → ← Discordant results. DBP, diastolic blood pressure; SBP, systolic blood pressure.

Concerning metabolic disorders, although IVF–ICSI offspring displayed comparable BMI (-0.04 kg/m^2 , $P = .20$), differences in body composition and signs of metabolic dysregulation were noted in ART-conceived children and adolescents (Guo et al., 2017). Ceelen et al. reported that IVF children had significantly more peripheral body fat assessed by skinfold thickness and dual-energy X-ray absorptiometry (DXA), even after adjustment for antenatal and parental factors, and despite minimal differences in BMI as compared to children born to subfertile parents (Ceelen et al., 2008a,b, 2009). Similar observations were made in pubertal ICSI singleton girls (Belva et al., 2012). Specifically, ICSI-girls aged 14 years old had increased peripheral, central, and total adiposity, while only increased peripheral adiposity was observed in ICSI singleton boys at an advanced pubertal stage. Conversely, Miles et al. found no difference in fat percentage by DXA between 4 and 10 year-old IVF children and NC controls (Miles et al., 2007).

Additionally, some reports have suggested that ART may also impair glucose metabolism, potentially as a result of increased adiposity. Two studies reported higher fasting glucose levels (Ceelen et al., 2008a,b; Pontesilli et al., 2015) and one, a lower peripheral insulin sensitivity in ART-conceived children (Chen et al., 2014) (Fig. 2). However, all of the other cohort studies did not report any difference in glucose and insulin levels according to the mode of conception (Sakka et al., 2010; Scherrer et al., 2012; Green et al., 2013; Chen et al., 2014).

Concerning lipids profiles, the results are reassuring as lower LDL cholesterol levels were reported in IVF children (weighted mean difference -0.10 mM ; 95%CI $[-0.19, -0.01]$) and triglycerides and HDL/total cholesterol levels were similar to those in controls (Guo et al., 2017).

Childhood Cancers

Most cohort studies that examined the cancer risk in ART children demonstrated that ART procedures were not associated with an increased risk of cancers overall (Reigstad et al., 2017). For instance, one data linkage study that included 25,782 ART children with a median follow-up of 6.9 years showed that ART children did not have a significantly increased incidence of cancer (Reigstad et al., 2016). A similar conclusion was reported in a Nordic cohort study over a longer follow-up (in 91,796 ART children over an average follow-up of 9.5 years—Sundh et al., 2014) as well as in an Israeli study (9042 ART children over a median follow-up of 9.3

years—Lerner-Geva et al., 2017). Only one of the larger cohort studies detected a significantly higher risk of overall cancer in children conceived by ART (OR 1.42; 95% CI [1.09, 1.87]) (Kallen et al., 2010). However, some studies have reported an increased risk of specific cancer types such as hematological, neurological, and rare cancers.

The two metaanalyses based on 25 and 23 cohort studies concluded that there was a higher risk of hematological cancers in children conceived after ART (Fig. 2) (Hargreave et al., 2013; Reigstad et al., 2017).

Data on neurological cancers are scarce. However, a large retrospective study reported an increased risk in ART children for central nervous system (CNS) tumors (adjusted HR 1.44; 95%CI [1.01, 2.05]) and malignant epithelial neoplasms (adjusted HR 2.03; 95%CI [1.06, 3.89]), after adjusting for country, maternal age, parity, year of birth, sex, gestational age, and birth defects (Sundh et al., 2014). Conversely, these findings were not confirmed by two other large cohort studies (Williams et al., 2013; Reigstad et al., 2016). However, as CNS cancer is most frequent in older children and adolescents, a longer follow-up is needed.

A few case reports have indicated a potential increased risk of retinoblastoma and hepatoblastoma in ART children (Marees et al., 2009; Williams et al., 2013; Lerner-Geva et al., 2017). However, it is difficult to draw any conclusions on these rare forms of cancer. In addition, some of these studies lacked statistical power and were limited by a short follow-up.

Mental Health Outcomes

Cerebral palsy (CP) is a rare but serious neuromuscular disorder that affects the development of movement and posture, with a prevalence of about 2 per 1000 live births. In several studies, a higher risk of CP was reported following ART (Pinborg et al., 2003; Lidegaard et al., 2005; Hvidtjørn et al., 2006, 2009; Klemetti et al., 2006; Goldsmith et al., 2017). The authors concluded that this could be explained by a higher frequency of preterm birth, multiple pregnancies or vanishing embryos in ART pregnancies (Hvidtjørn et al., 2005, 2009; Pinborg et al., 2005). As Zhu et al. did not find any effect of time to pregnancy on the risk of CP they concluded that the effect of ART treatments could be more important than that of parental subfertility. One metaanalysis on singletons reported an increased risk of CP after ART (OR 1.82; 95%CI [1.31, 2.52]) (Hvidtjørn et al., 2009).

The last review on cognitive outcomes in children conceived following ART reported discrepant results among five high-quality studies (Rumbold et al., 2017). Indeed, three studies found no difference (Pinborg et al., 2003; Wagenaar et al., 2009; Bay et al., 2013b) whereas two studies reported poorer cognitive ability in ART infants than in NC infants (Strömberg et al., 2002; Sandin et al., 2013).

Moreover, among studies that assessed the impact of the mode of in vitro fertilization and rated as high quality, one out of three found a 50% increase in the risk of mental retardation in children conceived by ICSI as compared with children conceived with IVF (Sandin et al., 2013).

Concerning the association between the use of ART and the risk of autism spectrum disorders (ASD), several studies, either case-control or cohort studies, have been inconsistent in their findings. Nevertheless, the recent review of Liu et al., which summarized 11 previous studies involving more than 8 million patients, concluded that ART is likely to be an independent risk factor for ASD in ART children ($RR = 1.35$; 95%CI [1.09, 1.68]) (Liu et al., 2017).

However, a recent review of the literature provided reassuring evidence on socio-emotional, cognitive, behavioral, and psychomotor development for preschool and middle childhood ART children (Bay et al., 2013a). Nevertheless, very few studies have assessed this development among teens, and their results were also inconsistent. On the other hand, Ilioi et al. reported that IVF-conceived adolescents did not show differences in emotional or behavioral problems as compared with NC controls (Ilioi and Golombok, 2015) (Fig. 2).

Epigenetic Risk

Even though contradictory findings exist, several reports pointed toward an increased risk of diseases caused by abnormal genomic imprinting. Indeed, the relative risk for the birth of a child with Beckwith–Wiedemann syndrome was 5.2 (95%CI [1.6, 7.4]) following ART compared with the risk in the normal population (Fig. 2). This excess of imprinting disorders following ART, as well as the fact that all ART-BWS cases typically occur through loss of DNA methylation in imprinting control regions raises the issue of a potential epigenetic risk induced by ART techniques. Concerning Silver–Russell syndrome, as it is extremely rare, it is difficult to draw any conclusions, but a positive association with IVF or ICSI treatment is likely. No significant associations were found between the incidence of Angelman and Prader–Willi syndromes and IVF or ICSI treatments. Fertility problems could be involved in these latter syndromes in ART children.

Conclusion

In summary, this review underlines discrepancies between results in the various health domains studied, making it difficult to draw reliable conclusions. The majority of studies did not have a robust methodology and included several potential confounders associated with the studied populations (Fig. 1). These may be due to differences in the ages investigated, the study period and design, the inclusion criteria of subjects and the comparison group, sample size, parental characteristics, and the ART technique employed. Thus, it is challenging to interpret and analyze the data as they are heterogeneous and prone to various biases.

Nonetheless, it seems that individuals conceived by ART may have an increased risk of cardiovascular and metabolic diseases, hematological cancers, cerebral palsy, and autism. Other health issues found in childhood, such as growth and pubertal development, need to be investigated further. It is also crucial to have studies with a longer follow-up and continuing into adulthood to assess the risk of late-onset diseases (such as oncogenic, cardiovascular, metabolic, and neurological diseases) and fertility. It is still unresolved whether the ART procedures or subfertility led to some of these changes. In addition, ART includes the use of several techniques such as ovarian stimulation, embryo culture (short or extended embryo culture up to the blastocyst stage, type of culture medium) and embryo transfer (fresh or frozen embryos). Notably, the culture medium (Zandstra et al., 2015; Bouillon et al., 2016) and the transfer of frozen embryos (Pinborg et al., 2014) could have an impact on birth weight or developmental age. It is thus important to distinguish their respective impact on the health of infants thus conceived.

Moreover, some of these changes could be related to multiple pregnancies and low birth weight, which are more frequent in ART pregnancies and associated with an increased risk of adverse obstetric and neonatal outcomes. In recent decades, it has been reported that these environmental changes during early development could have adverse effects on health in later life. Thus, further prospective, large and high-quality studies in the long term are necessary to ensure that ART methods, which are recognized as being effective, are also safe for the future health of adults and for future generations.

Glossary

Assisted reproductive technologies (ART) All technological tools, surgical procedures, and medical treatment modalities used to achieve pregnancy.

Cryopreservation A specific procedure in which various chemical solutions and anti-freezing molecules are used to preserve cells or tissues by cooling to very low temperatures below zero.

Gamete cryopreservation Cryopreservation of egg or sperm cells.

Gonadal tissue cryopreservation Cryopreservation of ovarian or testicular tissue.

In vitro fertilization (IVF) The process in which an oocyte and a sperm are fertilized outside of the body.

Intracytoplasmic sperm injection (ICSI) An advanced IVF technique in which a single sperm is directly injected into an oocyte cytoplasm.

Ovarian stimulation An ART technique introduced to induce development of multiple ovarian follicles using various fertility medications.

Preimplantation genetic diagnosis A genetic profiling technique used to screen embryos for specific genetic diseases prior to implantation.

Introduction

In 1972, for the first time, Patrick Steptoe and Robert Edwards developed a human embryo in a petri dish. In the next four decades, assisted reproductive technologies (ART) resulted in more than 6 million children born around the globe. For achieving a healthy pregnancy, ART consists of a numerous procedure including ovarian stimulation, in vitro fertilization (IVF), intra-cytoplasmic sperm injection (ICSI), gamete and embryo cryopreservation, gonadal tissue cryopreservation, and preimplantation genetic diagnosis. All these methods usually require stimulation of ovaries using special medications as an initial step towards a desired pregnancy. The goal of ovarian stimulation is to induce development of multiple follicles with mature oocytes in order to improve the chances obtaining a viable embryo. For this purpose, several fertility drugs have been introduced and utilized in the treatment of thousands of women with fertility issues including those with cancer history. Hence, it has been questioned whether inducing multiple ovulations by fertility drugs and alterations in endogenous sex steroid levels may have an association with an increased risk of developing cancer.

In this article, we review the current knowledge examining the relation between the use of fertility drugs for ovarian stimulation and the risk of cancer. In the first section, we summarize the available data on the risk of cancer occurrence after use of fertility drugs, and in the second section we evaluate the risk of recurrence in women with history of cancer.

Long-Term Risk of Cancer After Ovarian Stimulation With Fertility Drugs

The concept of ovarian stimulation using fertility drugs such as clomiphene citrate or gonadotropins is of the main premise behind infertility treatments. Fertility drugs can be used to restore cyclic ovulatory function in anovulatory infertile women or to stimulate development of multiple ovarian follicles for higher oocyte yield in IVF treatments. According to most recent statistical reports, approximately one million IVF cycles and even larger numbers of ovulation induction cycles are being performed every year in the United States. While the use of fertility drugs is becoming increasingly common, some clinical studies suggested a possible link between fertility drugs and various types of cancers such as breast, endometrium, ovary, cervix, colon, and thyroid (**Table 1**).

Breast Cancer

Breast cancer is the most commonly diagnosed cancer and is the leading cause of cancer-related death in women in the world. According to National Cancer Institute's SEER database from 2007 to 2011 on average more than 25,000 women are diagnosed with breast cancer before reaching the age of 45 years, each year in the United States. Although the central underlying etiological factors in the development of breast cancer are not fully understood, it is well acknowledged that there are multiple genetic and environmental factors that are predisposing. Advanced age, ethnicity, BRCA gene mutations, family history of breast cancer, and ionizing radiation are known risk factors. Among the others, exposure to estrogen has been suggested as a primary promoter of

Table 1 Currently available evidence for the suggested link between fertility drugs and various types of cancer

<i>Fertility medications</i>	<i>Drug effect</i>	<i>Investigated malignancies</i>	<i>Current evidence</i>
• Clomiphene citrate • Gonadotropins (rFSH, rLH, HMG)	• Multiple ovulation • Increased serum estradiol • Increased serum progesterone	• Breast cancer • Endometrial cancer • Ovarian cancer • Cervical cancer • Colon cancer • Malignant melanoma • Thyroid cancer • Non-Hodgkin lymphoma	No sufficient evidence for increased risk with fertility drugs

FSH, Follicle stimulating hormone; *rFSH*, recombinant FSH; *LH*, luteinizing hormone; *rLH*, recombinant LH; *HMG*, human menopausal gonadotropin.

breast cancer. During ovarian stimulation cycle, along with multiple developing follicles in the ovaries, endogenous production of estrogen is increased on average up to 10 times higher level than the levels in natural menstrual cycle. Therefore, stimulation of ovaries using fertility medications has been argued as an emerging risk factor for breast cancer development. However, ovarian stimulation is also associated with an increase in exposure to progesterone hormone via multiple ovulations. Parity, which is characterized as a state of high progesterone levels, is associated with a lower risk of breast cancer, hence some researchers proposed progestogens as effective treatment options in breast cancer. On the other hand, in some experimental studies, progesterone was reported to drive tumoral cell proliferation in breast cancer cell lines. Regardless of the controversial role of progesterone in breast cancer, it should be noted that fertility drug in single cycle use results in high levels of hormones for a short period of time and prolonged exposure must involve numerous cycles of fertility drugs.

Several studies have investigated the relationship between fertility drugs and breast cancer. The majority of those investigations, including large cohort studies with up to 30 years of follow-up, have either shown no significant increase in the risk of breast cancer or a decrease in risk following infertility treatments when compared with either women with infertility who did not undergo treatment with fertility medications or the general population. Based on the current evidence, fertility drugs appear not to be associated with a significant risk of breast cancer.

Gynecological Cancers (Endometrium, Cervix, and Ovary)

Endometrial cancer is the most common uterine cancer and its association with unopposed estrogen exposure is well established whereas progesterone is reported to be a protective factor. Hence, it is plausible to suggest that fertility drugs could either increase the incidence of endometrial cancer due to increased estrogen production or decrease the incidence of endometrial cancer secondary to the protective effect of progesterone released following ovulation during luteal phase. However, studies addressing the risk of endometrial cancer after use of fertility medications are also limited by methodological issues. First, infertility has been shown to be an independent risk factor for endometrial cancer regardless of fertility drug use. Second, most cohort studies reported on small numbers of women, short or incomplete follow-up, and inadequate methods to control for potential confounders such as anovulation, hormonal therapy, metabolic syndrome, and hysterectomy. Nevertheless, the majority of studies and meta-analyses showed that the overall use of fertility drugs, specifically clomiphene citrate, gonadotropins, and IVF treatment in general, is not associated with a significant increased risk for endometrial cancer.

Among all gynecological malignancies, ovarian cancer is the deadliest cancer and accounts for about 3% of all cancers in women, with approximately 20,000 cases diagnosed annually in the United States. Nulliparity is one of the main risk factors for the disease, hence women with infertility are considered to be at an increased risk for ovarian cancer. On the other hand, pregnancy and the use of ovarian suppressing medications such as oral contraceptive drugs have been observed to decrease the incidence of the disease. To be able to explain the biological mechanism behind the development of ovarian cancer, the theory of “incessant ovulation” has been proposed by Fathalla in 1971. This theory suggests that ovarian cancer primarily originates from the epithelium that covers ovarian surface and tumorigenesis is initiated by follicular rupture during ovulation which causes repeated damage and repair cycles in disrupted epithelial tissue. According to this hypothesis, years of prolonged and uninterrupted ovulation may increase the risk of

ovarian cancer by repetitive trauma to the epithelial cells. Following that logic, it was hypothesized that induction of multiple and repetitive ovulations with fertility drugs may increase the risk of ovarian cancer development. However, this long-standing theory has been recently challenged by the accumulating evidence that aggressive ovarian cancers originate in other pelvic organs and involve the ovary secondarily. The most recent studies revealed that the fallopian tube epithelium is the primary origin of high-grade serous ovarian cancers. Therefore, the incessant ovulation theory appears to have insufficient base to suggest a link between fertility drugs and ovarian cancer.

When the studies considering the relationship between fertility drugs and invasive ovarian cancer are analyzed, several methodological issues arise including lack of proper controls, failure to control confounding factors known to influence cancer risk, and lack of long-term follow up. Despite the earlier studies suggesting an association between fertility drugs and invasive ovarian cancer, recent investigations with better study design, as well as several systematic reviews and/or meta-analyses have shown no significant increase in the risk of invasive ovarian cancer following the use of fertility drugs when compared with infertile controls and/or with the general population.

Though there is insufficient evidence to establish a link between fertility drug use and invasive ovarian cancer, some studies have shown an association between the utility of fertility drugs and borderline ovarian tumors. Borderline ovarian tumors are of low malignant potential with a 95% 5-year-survival rate, and contrary to invasive ovarian cancers, they are more likely to be diagnosed in women of reproductive age. However, based on the available data, there is insufficient evidence to suggest that using fertility drugs increases the risk of borderline ovarian tumors.

Regarding cervical cancer, the second most common gynecological cancer, several studies found no increased risk with fertility drug use when compared to the general population as well as patients with infertility.

Other Types of Cancer

In addition to breast and gynecological cancers, researchers have also investigated whether use of fertility drugs may increase the risk of other types of cancer such as colon, thyroid, malignant melanoma, and non-Hodgkin lymphoma. Although in some experimental studies female sex steroids have been reported to cause altered tumoral progression in some of these cancers, majority of clinical studies have found no increase in the incidence of those cancers in patients undergoing IVF treatments compared to general population.

The Long-Term Risk of Recurrence in Cancer Patients After Ovarian Stimulation

Cancer is a global health problem and an important cause of morbidity and mortality in reproductive age women. Cancer treatments including chemotherapy and radiotherapy have been shown to damage ovarian follicles and cause premature ovarian failure. Additionally, increasing number of women delay childbearing due to various reasons that has made fertility preservation a major issue for young women with cancer. Hence, several treatment options for young women with cancer have been developed to preserve their future chance of having children. Embryo cryopreservation after IVF is currently considered as an established fertility preservation option, which offers the best chance of livebirth for women with a partner or single women who elect to use donor sperm. Cryopreservation of mature eggs is another fertility preservation option for women without a partner and those who not wishing to use donor sperm due to legal, ethical, or religious considerations. However, these established methods typically require controlled ovarian stimulation in order to obtain mature eggs. Since ovarian stimulation is known to elevate circulating estrogen and progesterone levels, it has been considered unsafe in women with estrogen-sensitive cancers.

Breast Cancer

The relation between breast cancer and estrogen is well-known and the major issue associated with the conventional ovarian stimulation protocols is elevated circulating estrogen levels due to the development of large number of follicles at once. Therefore, conventional stimulation treatments are considered unsafe in women with estrogen-sensitive breast cancer. As a response to these concerns, we have developed new and effective ovarian stimulation protocols for breast cancer patients using Tamoxifen and Letrozole, which are normally used in the endocrine treatment of estrogen sensitive cancer.

Tamoxifen is an estrogen receptor modulator and can be used either alone for ovulation induction or in combination with low dose gonadotropins for IVF. Letrozole is an aromatase inhibitor that reduces estrogen production by blocking the enzyme that converts androgens to estrogen. By reducing the circulating estrogen levels, aromatase inhibitors induce a surge in FSH production from the pituitary gland, which in turn stimulates ovarian follicle development. We found that letrozole in combination with gonadotropins can produce comparable or better IVF outcomes to conventional ovarian stimulation protocols while providing significantly lower estrogen levels and decreased gonadotropin requirements in premenopausal breast cancer patients. Furthermore, after short and mid-term follow up, we showed that letrozole-gonadotropin combination protocol was not associated with any reduction in disease free survival rates.

Gynecological Cancers

Gynecological cancers are commonly seen in the late stages of life; however, a significant number of affected women are of reproductive age. Young women are likely to present with earlier stage of gynecological cancer, which can be cured with fertility sparing

surgeries and treatments. For those women embryo and oocyte cryopreservation following ovarian stimulation are suitable options for fertility preservation. A currently experimental procedure, ovarian tissue cryopreservation and subsequent transplantation is also promising option for those who are not eligible for ovarian stimulation. Although current data on ovarian stimulation after gynecological cancer treatment is limited to very few case reports or case series, ART seems to not have any adverse effect on disease free survival. Furthermore, using letrozole protocol in ovarian stimulation may have protective effect in estrogen-sensitive gynecological cancers.

Other Types of Cancer

There is insufficient data regarding the use of fertility drugs and the recurrence of cancers other than breast and gynecological cancers.

Summary

Despite the plausibility of postulated biological mechanisms, several clinical studies examining the relationship between fertility drugs and cancer found conflicting results; some studies reporting a possible increased or decreased risk, while others showing no effect. It should be emphasized that examining the relationship between fertility drugs and cancer is a difficult task due to numerous confounding factors and methodological limitations. For example, while nulliparity is considered as a risk factor for development of breast, endometrial and ovarian cancer, successful fertility treatments should in theory reduce the risk of these cancers by enabling these women to become fertile. In addition, most studies lack of long-term follow-up to capture the age at which these diseases commonly occur. Another limitation is that the medications used in the treatment of infertility have changed over the past years, which makes the interpretation of long term data challenging. Finally, it is plausible that infertility and cancer may have shared pathways. We showed that women with BRCA mutations have accelerated ovarian aging. Hence the observations of cancer in an infertile population may simply be due to the factor that these two conditions are manifestations of the same underlying disorder, that is deficient DNA repair, rather than one causing the other.

In conclusion, controlled ovarian stimulation particularly in combination with aromatase inhibitor appears to be safe protocol for women who are concerned about the added estrogen exposure from fertility treatments. Current evidence suggests that infertile women may be at an increased risk for various types of cancer, however the use of fertility drugs for ovarian stimulation is not associated with a significant risk of occurrence or recurrence.

Cost-Effectiveness of High Versus Low Complexity ART Treatments

Nina Resetkova and Ashley Aluko, Beth Israel Deaconess Medical Center, Boston IVF, Waltham, MA, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Cost effectiveness is an elusive topic within the pages of reproductive journals. Most clinicians and scientists have limited formal training in healthcare economics and often hesitate to read and interpret studies on cost effectiveness. In addition, many are skeptical of this area of research as conclusions can be based on variables chiefly selected to influence the desired outcome. However, there can be a lot of practical application drawn from well-constructed cost effectiveness studies. The examination of key issues within our field from the viewpoint of total cost to the system, to the patient, or to the clinic is a timely topic in this age of emerging new and often expensive technologies. This is especially relevant given the seemingly unending age of cuts to reimbursements in modern healthcare systems.

The purpose of this article is to compare the cost effectiveness of low and high complexity artificial reproductive technology (ART) treatment strategies. As new technologies and medications are brought to market, they should be critically compared to established therapies. In low resource settings in particular, healthcare costs are more trackable and have been frequently studied. However, with rising costs of care in developed nations, it is also important to consider the value proposition of ART innovations in these settings.

Although randomized controlled trials (RCT) are the gold standard for evaluating the efficacy of new treatments or interventions, they are labor and time intensive, and simply do not exist in certain subject areas. This article provides a broad overview of available studies of varying design and methodology, as these serve as a helpful initial study tool in evaluating the cost effectiveness of new treatments.

What is a Cost Effectiveness Analysis

Cost effectiveness analysis (CEA) is a form of economic analysis that compares the relative costs and outcomes of two or more courses of action. The most commonly used outcome measure is the quality adjusted life year (QALY). The QALY is a generic measure of health-related quality of life that takes into account both the quantity and quality of life generated by interventions.

Another important concept to understand when reading and interpreting CEA's is the ICER (incremental cost effectiveness ratio). An ICER is calculated to provide the net difference in costs divided by the net difference in benefits when the net costs and benefits are compared to a competing strategy. The concept of value is related to the ICER, since members of a society, social group, or workplace may place emphasis on certain metrics. For example, in some high resource countries efficacy is valued over cost effectiveness, and society is willing to pay more for a higher chance of cure, live birth, or other positive outcome.

CEA is often used in the field of health services, where it may seem inappropriate to monetize health effect. In contrast, cost benefit analysis (CBA) is favored in public services projects, such as the construction of a dam or road, where monetizing outcomes or effects is more straightforward. Notably, CBA does not take into account the quality of life of an individual. Other forms of economic analyses that may be applied in health care analysis include cost-utility analysis and direct analyses of associated costs.

Cost Effectiveness Analysis in Reproductive Medicine

In order to provide a methodical review of cost effectiveness studies in our field, we approached this article by grouping and analyzing studies according to diagnosis. You will find that certain topics have been more extensively studied than others, lending to more reliable input data (the probabilities entered into a cost effectiveness model). Generally speaking, the conclusions that can be generated from a CEA are as good as the quality of the data or assumptions that are made in constructing the model.

There are some research areas in which several papers have all come to similar conclusions, however there are other areas in which there has been extensive discussion with conflicting published results. Gaps in the topic areas discussed below reflect a lack of robust data, which logically extends that more research is needed to draw any further conclusions. We conclude with an overview of the cost-based studies performed in regions with emerging economies, the majority of which examine the necessity of intervention as compared to expectant management, or a low complexity intervention to one involving moderate to high complexity, such as an IVF laboratory. A review of strategies employed for cost containment in emerging economies can serve as a helpful reminder of which testing and treatments are truly essential.

Male Factor Infertility

Male factor infertility affects 15% of men and contributes to a couples' inability to conceive in approximately 50% of cases (Turek, n.d.). ART such as intrauterine insemination (IUI), in vitro fertilization (IVF), intracytoplasmic sperm injection (ICSI), and artificial insemination with donor semen, has revolutionized treatment of male factor infertility. Though these technologies are widely utilized, there are few randomized controlled trials validating their cost effectiveness in the setting of male factor infertility.

Studies comparing the cost effectiveness of IUI and IVF in male factor subfertility and unexplained fertility yield conflicting results. Goverde et al. concluded that initiating fertility treatment with an IVF cycle is more cost effective than IUI followed by IVF (Goverde et al., 2000). On the contrary, Pashayan et al. found that IUI and IVF conferred a similar chance of a successful pregnancy, and deemed IUI the more cost effective approach (Pashayan et al., 2006). There are no clearly defined algorithms to determine which patients with male factor infertility are more likely to benefit from initial treatment with IUI or IVF, however it is logical that certain semen parameters portend a poor prognosis when IUI treatment is chosen as the first step. In a decision analysis model of couples with male subfertility, if the pre-wash total motile sperm count (TMSC) was over 3 million, the cost per live birth was lower for IUI with ovarian stimulation than for IVF. However, below a pre-wash TMSC of 3 million, IVF/ICSI treatment resulted in a lower cost per live birth (Moolenaar et al., 2015). This lends a helpful approach to treating couples with a mild male factor infertility when cost effectiveness is deemed a priority.

Fertility After Vasectomy

In patients who desire fertility after a vasectomy, vasectomy reversal is considered a less-costly alternative to IVF, especially when performed by a skilled microsurgeon. An early study on fertility options after vasectomy compared the cost per delivery after vasectomy reversal (\$25,475) and sperm retrieval plus ICSI (\$72,521). The authors calculated a delivery rate of 47% after a vasectomy and 33% after a single cycle of sperm retrieval and ICSI, and concluded that vasectomy reversal was more cost-effective (Pavlovich and Schlegel, 1997). This historical study, published in 1997, may have overestimated the cost and underestimated the effectiveness of ART, as innovations over the last 20 years have improved IVF outcomes and reduced procedural costs. Regardless, contemporary cost effectiveness data generated from decision analysis models still favors vasectomy reversal over ART (Robb and Sandlow, 2009; Lee et al., 2008; Meng et al., 2005). A 2005 study estimated the cost per delivery for vasectomy reversal versus sperm retrieval with ICSI to be \$38,983 versus \$39,506, respectively. In this study, in order for vasectomy reversal to be more cost effective than IVF with ICSI, a threshold patency rate of 78% had to be established. Parameters associated with higher patency rates include shorter obstructive interval and ability to perform bilateral vasovasostomy (Meng et al., 2005).

Although it appears as though vasectomy reversal is more cost effective than IVF, providers must carefully consider the female partners' reproductive capacity, interval of time that has passed since vasectomy, and the etiology of male factor infertility, as these factors play a role in the ability to conceive after a vasectomy reversal. Often, despite initial treatment with vasectomy reversal, couples with obstructive azoospermia due to vasectomy will go on to require IVF (Chiles and Schlegel, 2015). While vasectomy reversal can be considered a cost effective alternative to IVF, it is imperative to carefully select couples who would benefit most from this approach.

PCOS and Anovulation

Polycystic ovarian syndrome (PCOS) affects 5%–10% of reproductive aged women and is a major contributor to anovulatory infertility (Tarlitzis et al., 2008). Ovulation induction with clomiphene citrate (CC) is widely regarded as first line pharmacologic therapy due to low cost, ease of administration, favorable side effect profile, and infrequent need for ovarian response monitoring. Up to 80% of women with PCOS ovulate with CC, and of those who ovulate the conception rate is 22% per cycle (Tarlitzis et al., 2008). For patients who fail to conceive with CC, second-line options include exogenous gonadotrophins and laparoscopic ovarian surgery, with the latter performed less frequently due to potential complications of surgery (Tarlitzis et al., 2008). Administration of exogenous gonadotrophins for ovulation induction is more costly than CC and requires ovarian response monitoring to mitigate the risk of ovarian hyperstimulation syndrome (OHSS) and multiple gestation pregnancies (Eijkemans et al., 2005). In patients with anovulatory infertility who fail to conceive with CC, exogenous gonadotrophins, or laparoscopic ovarian surgery, IVF remains a viable, though significantly more costly, option (Tarlitzis et al., 2008).

Eijkemans et al. sought to develop an algorithm for an individualized strategy to treating anovulatory infertility in a cost effective manner. The authors determined that using a stepwise approach, with first CC, then gonadotrophins, and finally IVF was cost-effective for women less than 30 years old with normal androgen levels. In women over 30 years old with elevated androgen levels, proceeding with IVF (rather than gonadotropin treatment with IUI) when CC fails to produce conception was most cost effective (Eijkemans et al., 2005).

In a decision analysis model of women with PCOS who did not conceive after six cycles of CC, continuation of CC for six cycles followed by three cycles of IVF was the least costly scenario, with a two-year birth rate of 74%. Continuing CC for three cycles, followed by six to twelve cycles of gonadotropins then three cycles of IVF "in case of no live birth," was found to be more expensive, but also more efficacious (93%–98% live birth rate) (Moolenaar et al., 2014). One limitation of this study, and others within the area, is that it assumed a steady pregnancy rate over the course of IUI cycles, which does not mirror the attrition in success rates typically observed in clinical practice.

Aromatase inhibitors such as letrozole have been investigated for use in ovulation induction, either as an alternative to CC or for CC-resistant patients (Casper and Mitwally, 2012). An RCT comparing the cost effectiveness of letrozole and purified urinary FSH in CC-resistant PCOS demonstrated no difference in ovulation and clinical pregnancy rate, however FSH cycles were almost five times more expensive. Although in this study letrozole was found to be more cost effective than FSH in treating CC-resistant PCOS, further research on this topic is necessary (Hassan et al., 2017).

Tubal Factor

Options for women seeking fertility after tubal ligation include tubal anastomosis and IVF. Maternal age is the most important prognostic factor in pregnancy rates after tubal anastomosis (ASRM Committee Opinion, 2012), thus most studies on this topic stratify patients by age.

A recently published cost and efficacy comparison study found that tubal anastomosis was more cost effective than IVF for women under the age of 41. They reported that for women over age 40, tubal anastomosis remained the most cost effective option only when IVF costs exceeded \$30,000 per cycle. This particular study quoted the cost per pregnancy as \$16,315 (age < 35), \$23,914 (age 35–40), and \$218,742 (age > 40) after tubal anastomosis and \$32,814 (age < 35), \$45,839 (age 35–40), and \$114,445 (age > 40) after IVF (Messinger et al., 2015). This study focused on a United States-based population, however its re-analysis in different regions of the world would lead to valuable and likely differing conclusions based on varying inputs of cost of treatment, surgery, and IVF success rates.

Certain tubal ligation techniques, including those that do not require removing a large segment of fallopian tube, are more amenable to anastomosis than others. Hirschfield-Cytron et al. found that across all age groups, anastomosis after a favorable ligation technique (ex. clip, ring) was cost effective. In addition, tubal anastomosis, regardless of type of prior tubal ligation, was found to be more cost effective than IVF in all age groups, including women over age 40, as long as IVF costs exceed \$4500 (Hirschfeld-Cytron and Winter, 2013). These results contrast to the study by Messinger et al., which may reflect the differences in study design, as well as improved IVF success rates over the years between the studies were published.

While limited data suggests that tubal anastomosis is more cost effective than IVF, especially in younger women, there are no RCTs evaluating the relative cost effectiveness of each strategy. Treatment decisions should reflect an individualized approach because many parameters, specifically surgeon experience, maternal age, future pregnancy plans, and ovarian reserve, can impact the cost effectiveness of each technique.

Unexplained Infertility

Thirty percent of couples that fail to conceive are ultimately diagnosed with unexplained infertility (ASRM Practice Committee, 2006). These patients are often treated empirically with IUI, ovulation induction, or IVF, however expectant management remains a reasonable option with a shorter duration of infertility. A United Kingdom-based RCT of patients with unexplained infertility found that IUI and ovulation induction with CC was less cost effective than expectant management, with calculated costs per live birth of 72 pound sterling with expectant management, 1487 pound sterling with IUI, and 2611 pound sterling with CC (Wordsworth et al., 2011).

While expectant management may be more cost effective in certain situations, some patients, especially those with any concern for diminishing ovarian reserve, may be more suited to active management. Studies comparing the cost effectiveness of IUI and IVF in male factor subfertility and unexplained fertility yield conflicting results. While some studies suggest that starting treatment with IVF, as opposed to IUI followed by IVF, is more cost effective, others have found that IUI and IVF confer a similar chance of a successful pregnancy, favoring IUI as the more cost effective approach (Goverde et al., 2000; Pashayan et al., 2006).

Because poor fertilization may play a role in unexplained infertility, ICSI is sometimes performed in these cases. In one study that compared IVF, split IVF-ICSI, and ICSI in couples with unexplained infertility, IVF alone (\$13,842 per live birth, 38.8% likelihood of a live birth) was the most cost effective option if only one cycle was performed. The authors calculated an ICER of \$58,766 with split IVF-ICSI and all ICSI. They concluded that if two IVF cycles were necessary, split IVF-ICSI was the more cost effective approach (Vitek et al., 2013). The application of ICSI for IVF cycles with normal sperm parameters is controversial, thus decisions to institute treatment strategies should never be based solely on cost features, but instead requires attention and counseling on the risks and benefits of proposed strategies.

Interventions for treating patients with unexplained infertility range from very low cost (ex. expectant management) to high cost (ex. IVF with ICSI). With increasing interest in personalized medicine, further research is needed to guide clinicians in making economically-conscious decisions for these patients.

ART Versus Expectant Management, and Treatment in Low Resource Settings

The majority of couples with infertility reside in developing countries where advanced reproductive technology is either unavailable or prohibitively costly (Ombelet and Campo, 2007). Unfortunately, common causes of infertility in the developing world (i.e., tubal occlusion, severe oligospermia) are not amenable to conventional treatments such as CC and IUI, but instead require sophisticated, high complexity ART (Asemota and Klatsky, 2015; Dhont et al., 2011). Implementation of successful ART programs in low-resource settings necessitates a multifactorial approach to cost containment. This may involve simplifying the process of diagnosing

infertility, optimizing patient selection for treatment, maximizing non-IVF ART, utilizing alternatives to expensive ovarian stimulation protocols, and reducing laboratory and equipment costs. In addition, reducing costly complications such as ovarian hyperstimulation syndrome (OHSS) and multiple gestations should be emphasized (Ombelet and Campo, 2007; Teoh and Maheshwari, 2014).

A thorough medical history, in conjunction with simple and inexpensive investigative tools, often suffices in diagnosing infertility. Ombelet et al. proposed a one-step clinic model for basic infertility evaluation that utilizes infectious screening tests, hysterosalpingography and/or hysterosalpingo-contrast-sonography, and semen analysis. This initial workup will ideally identify most causes of infertility: ovulatory dysfunction, uterine malformations, tubal infertility, and male factor infertility (Ombelet and Campo, 2007).

Once initial diagnostic testing is completed, careful determination of which couples are most likely to benefit from expectant management can eliminate unnecessary interventions and costs. In a trial of couples with unexplained subfertility randomized to either 6 months of expectant management or immediate IUI with ovarian stimulation, there was no difference in pregnancy rate or time to ongoing pregnancy between groups. In fact, expectant management proved to be more cost effective, with an estimated saving of 2616 euros (Custers et al., 2012). When considering the cost effectiveness of IVF, one must not only take into account the procedural costs and anticipated success rates, but also a couple's chance of conception without treatment (Mol et al., 2000).

In patients who ultimately require IVF, natural cycle and low-dose ovarian stimulation protocols have been researched as potential alternatives to conventional IVF. Despite being low-cost and "patient-friendly," natural cycle IVF is not a widely utilized approach as its efficacy is limited by high cancellation rates due to premature LH surge and ovulation (Pelinck et al., 2002). Low-dose stimulation appears promising, but with lower success rates than conventional IVF (Asemota and Klatsky, 2015; Ombelet et al., 2008). In a study of couples undergoing IVF, those who underwent a low-dose stimulation protocol had similar clinical pregnancy rates, shorter gonadotrophin administration periods, and lower cost-per live birth (USD 13,200 versus 24,900) compared to those in the high-dose GnRH antagonist group. Low-dose stimulation was found to be more cost-effective, with the added benefit of a decreased incidence of OHSS (Chiles and Schlegel, 2015). Other options for low-dose stimulation protocols involve CC, letrozole, and gonadotrophins or recombinant FSH (Ombelet et al., 2008).

In addition to medications, laboratory and equipment fees are a major determinant of high IVF costs. Creative substitutions for expensive equipment can significantly reduce spending. For example, plastic incubators intended for newborns can be used in place of a laminar flow hoods for handling gametes and embryos (Asemota and Klatsky, 2015; Ombelet et al., 2008). Intravaginal and intrauterine fertilization and incubation methods have also been investigated (Ombelet et al., 2008). The INVO procedure, in which embryos are incubated within an intravaginal plastic device, there are comparable pregnancy rates to conventional IVF procedures (Lucena et al., 2012). The Walking Egg is a non-profit organization that pioneered a simplified IVF culture system which reduces the cost of a single IVF cycle to less than 200 euros (Ombelet, 2013).

There are several reports of successful ART programs in low-resource settings, including a public university hospital in Nigeria that offers IVF and ICSI. At this center, which has achieved a clinical pregnancy rate of 30% per cycle, patients are treated in batches to allow for bulk purchasing and reduced staff time. By implementing cost-saving measures, the cost per cycle for good responders is approximately \$3000—much less than the estimated cost of \$4000–5000 in other Nigerian clinics and \$12,000 in the United States. Sadly, in this particular center, even with these reduced costs, many couples were unable to afford a single attempt at IVF, and most who had an unsuccessful first cycle were unable to afford a second (Orhue et al., 2012). While affordable ART is possible in developing countries, further attention is necessary to make treatment of infertility more widely accessible to all.

Summary and Conclusions

As demonstrated in this article, there is extensive published data on cost effectiveness in reproductive medicine. However, it remains clear that studies evaluating fertility face specific challenges and limitations. From a 2014 paper by Goldhaber-Fiebert and Brandeau, the following were cited as criticisms of studies that affect fertility and childbearing, and were found to be consistently seen among the studies published over the preceding 40 years:

- Studies are heterogeneous in how they report outcomes
- Studies select outcomes that favor a cost effective conclusion
- Studies often report costs per immediate outcome
- Studies take different approaches to outcome inclusion
- QALY's related to pregnancy or fertility are often not addressed in interventions for which these are unintended/indirect outcomes

The paper recommended standardization in economic evaluations evaluating infertility and childbearing, with inclusion of all stakeholders, not just the individual carrying the pregnancy. The authors recommended the formation of consensus guidelines on how to count the impact of interventions that affect future fertility and childbearing (Goldhaber-Fiebert and Brandeau, 2015).

There are several base texts that provide excellent foundations for learning about how to construct and interpret cost effectiveness studies. Key resources include Drummonds Methods for the Economic Evaluation of Health Care Programmes (2015, Oxford University Press), as well as Muennig's Cost Effectiveness Analysis in Healthcare (2016, Wiley).

Increasing research interest, clinician awareness, and media attention to this area not only sparks further interest in cost effectiveness as a discipline of study within reproductive medicine, but also urges more providers to make care decisions with cost effectiveness in mind. In this vein, we would like to conclude with some key points to keep in mind when reading and interpreting CEA's. First, CEA studies are a moving target—as seen in some of the aforementioned studies, cost effectiveness of strategies can change over time. Second, one must remain cognizant of the fact that the current standard of care may not be cost effective. Third, it is worth reexamining processes proven to be cost effective in other countries, in order to see if previously held beliefs of what is cost effective still holds true.

Cost effectiveness studies can perhaps best be constructed from information derived from RCT's, but it is also true that cost based studies can help formulate the design of RCT's. RCT's are challenging to conduct in an area where patients can be very sensitive to cost, when there is an intrinsic belief that one treatment strategy is superior, and especially when the treatment in question is expensive to deliver. With increasing attention to the rising cost of care as addressed at the introduction of this article, it is worthwhile to consider calculating costs of treatment strategies in every RCT or comparable large scale study, even if that is not specifically related to the core focus or primary outcome of the study. The accumulation of more cost data can lead to downstream studies, help inform reporting about this important area, and derive data for future cost effectiveness studies.

Cost Effectiveness of Preimplantation Genetic Testing for Aneuploidy (PGT-A)

David Jimenez, Igenomix SL, Valencia, Spain

© 2018 Elsevier Inc. All rights reserved.

Among the genetic tests that nowadays are available for the patients of assisted reproduction, PGT-A (Preimplantation Genetic Testing for Aneuploidies) is the one that might generate more doubts about its cost effectiveness. During the last years, there are doubt between using PGT-A and adding to the total cost of the treatment a significant part or repeating transfers until the patient becomes pregnant. Both approaches will have the same objective, find the euploid embryo. However, deeper analysis is required to understand all the variables in order to have an informed decision both, from the clinic and for the patient point of view.

PGT-A

There is consensus that PGT-A might provide clinical benefits in a certain group of patients going through assisted reproduction (i.e., advance maternal age). However, there are also some drawbacks:

1. Higher level of complexity from the operations at the IVF lab
2. Affordability and cost effectiveness
3. Possible reduction of the clinic income
4. Non transfer dilemma
5. Ethical or religious aspects

We intend to provide some clarity specially in the cost benefit of the PGT-A.

The inclusion of PGT-A in the assisted reproduction treatment increases the complexity of the clinical process specially in the IVF lab due to the need of performing a biopsy to the embryo. Currently, several groups are researching about the possibility to diagnose the embryo trough the spent culture media, however, no publication has confirmed this option yet. So, until this possibility is not confirmed with solid data, embryo biopsy is required to provide the chromosome diagnosis.

The biopsy is a critical step in the PGT-A process and must be performed by expert embryologist ([Munne et al., 2010](#); [Harton et al., 2011](#)). One of the main explanation for some studies that did not find a better clinical result in patients of PGT-A versus regular IVF treatment might be the deficiency of the biopsy. A deficient biopsy will increase the stress of the embryo and might cause the failure of the whole treatment ([Cimadomo et al., 2016](#); [Capalbo et al., 2016](#)) due to the reduction of survival rate of embryos after the biopsy ([Swain et al., 2016](#); [Rubio et al., 2009](#)). In expert hands, the survival rate should be almost 100%.

Including PGT-A in a clinical IVF treatment requires that clinics increase the investment and personnel to be able to manage the PGT-A process mainly at the laboratory of IVF but also to provide to patients a proper genetic counseling before they accept and sign the consent form.

Affordability is the main barrier among clinicians to recommend the test. In general, PGT-A can increase substantially the total cost of the treatment that it is consider already a very expensive procedure for most patients. PGT-A cost has decreased in the last years thanks to the launch of new technologies and the appearance of new reference labs that has created a more competitive environment in most of the countries around the world. Additionally, the new trend to make the transfers the following month with frozen embryos allows reference labs to optimize their processes increasing productivity ([Weinerman and Mainigi, 2014](#); [Shapiro et al., 2014](#); [Roque et al., 2015](#)) while decreasing their prices.

To understand the cost of the PGT-A, several variables must be taken into consideration: the biopsy cost, the type of cycle (frozen vs. fresh), the technology used, the margin added by the clinic, the cost of the service provider and the cost of transportation of the samples from the clinic to the reference lab. The main cost elements are described below:

1. Intracytoplasmic sperm injection (ICSI): Although most of the clinics today include ICSI as a routine practice for any IVF cycle, PGT-A can be done only with ICSI to reduce the risk of sample contamination that could cause a misdiagnosis in the result of the test ([Mir et al., 2013](#)). In case a clinic does not routinely perform ICSI, it must be considered an extra cost versus a regular cycle without PGT-A.
2. Cost of biopsy: It is one of the most relevant factors of cost together with the genetic cost from the reference lab. It might be different if the biopsy is performed in day three versus in blastocyst stage.
 - a. Day-3 biopsy: The general trend is to choose the blastocyst stage at day-5 or 6 to perform the biopsy. In day 3, the embryologist can perform the process for all the embryos at the same time and this contributes to a reduction of lab consumables and embryologist time reducing the overall cost at the IVF lab. However, the average number of embryos that will be send to the genetic lab for testing will be higher in comparison to the number in blastocyst ([Rubio et al., 2007](#)) and therefore the savings might be balanced by the additional embryos that requires genetic test. In general, the genetic cost will depend on the number of samples sent to the reference lab.

- b. Trophoctoderm biopsy: As described above, the number of embryos to test is lower than in day-3. However, the protocol in day-5 requires more time from the embryologist and more consumable at the IVF lab since not all embryos can typically be biopsied at the same time (Scott and Hong, 2013). This factor increases the complexity of the process and the overall resources.
3. Frozen versus fresh transfer: The type of transfer also has an impact on the overall cost (Weinerman and Mainigi, 2014; Shapiro et al., 2014; Roque et al., 2015). Some publications suggest that a differed transfer might increase pregnancy rates due to the improvement of the endometrium versus a stimulated one. A frozen transfer will generate additional cost:
 - a. Vitrification consumables used in the process of freezing the embryos.
 - b. Labor resources at the laboratory.
 - c. Transportation cost to deliver samples to the reference lab. In case of fresh transfer, the transportation must be faster and more expensive due to the limited time for the whole process. On the contrary, when the samples are related to a frozen transfer, they can be send using a regular courier service reducing the cost significantly and allows the grouping of samples from several patients in the same shipment.
 - d. PGT-A related to frozen cycles allows to optimize the workload at the IVF lab and at the genetic lab. Transfers on weekends can be eliminated, night shifts at the genetic lab are also minimized reducing the overall level of stress for the teams.
4. PGT-A technologies: During the last years several technologies have been used to diagnoses embryos:
 - a. FISH (fluorescence in situ hybridization): It allows to diagnose a limited number of chromosomes and it is very manual requiring an expert team to achieve a consistent diagnosis. Since the introduction of arrays and NGS (next generation sequencing), FISH has lost relevance and only a small number of genetic laboratories still use it due to its clinical limitations. In addition, some publications suggest that using technologies that allows screening of 24 chromosomes increases the pregnancy rate. FISH is a labor-intensive technology making it expensive to use.
 - b. Arrays and QPCR: Both technologies have a similar cost structure and achieve 24 chromosomes. They allow some level of automation and it does not require so much labor resources to run the tests.
 - c. NGS: Since 2015, NGS has become the gold standard from the diagnosis point of view and from the cost. It allows to run many samples (i.e., 96 samples per run) and it also allows to automate the process at the wet lab part but also at the diagnosis process.
5. Pricing models from the genetic reference labs: Thanks to the introduction of NGS and the increase of the competition, prices for PGT-A in general have decreased in recent years. New pricing models are introduced to facilitate patients to afford the service: price per embryo, flat fees per patient independent of the number of embryos, batching programs, etc.

As described above, there are several factors that impact the cost of the PGT-A for a patient. In the following section a cost benefit model is described to help patients to take inform decisions regarding the convenience of the PGT-A not only from the clinical point of view but also from the financial one.

Cost Benefit PGT-A Analysis

The objective is to understand from the cost point of view if it is worthy for a couple to invest in PGT-A. Main variables of the model that will affect the cost benefit are:

1. Female age: Advance maternal age patients tend to have a higher percentage of abnormal embryos than a young patient. Therefore, a tool as PGT-A that helps to identify the normal embryo will reduce unsuccessful transfers, saving money and disappointments for patients.
2. Previous miscarriages: According to some publications the risk of Asherman syndrome increases with previous miscarriages history.
3. Male factor: Some publication also suggests that males with male factor (below 2 million sperm/mL) will generate a higher percentage of abnormal embryos.
4. Embryos to be transferred is also very relevant for the model. Single embryo transfer will need more transfers to find a normal embryo.
5. Some other variables also need to be considered as probability of miscarriage, probability of D&C procedure, probability of Asherman syndrome.

After defining a table of average abnormal embryo per age based on RCTs (randomized control trials), and retrospective data from genetic labs database from thousands of embryos from different clinics, the model can start assessing the relevant information to understand the clinical implications of PGT-A and the cost benefit analysis.

In the cost benefit analysis, the number of transfers is very relevant for the model. Generally, IVF centers include one transfer in the initial cost and every additional one has an extra cost for patients that can range from 20% to 30% of the initial price, like the cost of a PGT-A.

Below in **Tables 1 and 2**, an example is described to illustrate the model with a patient of 38 years old. We have not included the cost related to days lost due to miscarriage neither the estimated cost related to its psychological burden.

1. Cycle cost: Includes all services related to the treatment including one transfer.
2. Medication cost: Stimulation drugs.

Table 1 Example with a 38 years old patient with high ovarian reserve, male with normal sperm and without previous miscarriage

<i>Clinical data</i>	
Female age	38
Male sperm	Normal
Type of biopsy	Trophectoderm
Previous miscarriage	No
Expected number of blastocyst	4
Embryos to be transferred	1

Table 2 Example of cost of the clinic

<i>Cost data (euros)</i>	
Cycle cost	6000
Medication cost	1200
Extra transfer cost	1950
PGT-A cost	1500
Biopsy cost	700
Cost of amnio or NIPT	750

3. Additional transfers: Number of additional transfers until pregnancy.
4. Biopsy cost charged by the clinic to the patient that typically is a fixed amount independently of the number of embryos. We do not consider the vitrification cost since it is the same in both strategies, with or without PGT-A.
5. PGT-A cost: Cost of the genetic analysis including transportation of samples.
6. Cost of amniocentesis or NIPT (noninvasive prenatal testing): In case a PGT-A is not performed, a prenatal test should be recommended due to advance maternal age risk.

The model generates the information covering two dimensions: (1) clinical information and (2) cost information (**Table 3**).

1. % Aneuploid embryos: One of the most important information to determine the model. PGT-A effectiveness increases directly related to the increase of the percentage of aneuploid embryos.
2. Expected number of euploid embryos: Assessing the ovarian reserves it is possible to make a good estimation of the number of blastocyst that a patient of 38 years old will have for biopsy. In this example, the patient has a high reserve so 4 blastocysts are expected and 1.52 normal embryos ($4 \times 38\%$), a bit less (1.49) for PGT-A.
3. Probability to select an euploid embryo at initial transfer: It is accepted that morphology cannot predict the chromosomal profile of embryos. Using statistics, we can estimate the probability of selecting 1 normal embryo out of 4 available knowing that 1.52 are normal. In this case, the patients have 38% to select the normal embryo at first try.
4. Estimated number of transfers to select a normal embryo: With the information above and using hypergeometric distribution formula, we can define the number of transfer requested to find the euploid embryo. This is the most important variable of the model. This couple will need in average two transfers to find the normal embryo versus only one for the PGT-A.
5. Multiple pregnancy probability: IVF community is trying to promote single embryo transfer to reduce multiple pregnancies due to (1) complications and additional cost in multiple pregnancies and (2) health advantage of single vs multiple pregnancy babies.

Table 3 Clinical information

<i>Clinical information</i>	<i>Non PGT-A</i>	<i>PGT-A</i>
% Aneuploid embryos	62%	62%
Expected number of euploid embryos	1.52	1.49
Probability to select an euploid embryo at initial transfer	38%	99%
Probability of pregnancy at first transfer	23%	59%
Miscarriage probability	36%	8%
Multiple pregnancy probability	1.4%	1.4%
D&C probability	18%	4%
Asherman syndrome risk probability	3%	0,3%
Estimated number of months before baby at home	19.5	16
Estimated number of transfers to select a normal embryo	2.0	1

Table 4 Cost benefit analysis

	Non PGT-A	PGT-A
Cycle cost	6000	6000
Medication	1200	1200
Additional transfers cost	1995	0
PGT-A cost	0	2200
D&C cost	292	65
NIPT cost	492	0
Total cost	9487	9465

**Fig. 1** Distribution of cost according to maternal age.

6. D&C probability: It is important to calculate the cost associated to the higher probability of miscarriage and therefore D&C required. This couple will have a significant reduction of the risk of miscarriage from 36% to 8% when using PGS-A and also a consequent reduction on the D&C from 18% to 4%. According to the American Pregnancy Association, half of the miscarriages will require a D&C procedure.
7. Asherman syndrome risk probability: Transferring aneuploid embryos might have some relevant health consequences that patients need to understand: miscarriage, D&C and also Asherman syndrome. In this example the patient will have a risk of 3% or 10 times higher than with PGT-A (Friedler et al., 1993).
8. Estimated number of months before baby at home: Additional transfer means additional time to find the euploid embryo and therefore additional time to have the baby at home. According to some studies, the difference of time to obtain a baby at home between PGT-A and non PGT-A treatments is 100 days.

The cost benefit analysis is shown in Table 4. Using the data in the table above, we can calculate what will be the expected cost for a treatment including and not including PGS-A. In this particular example, the model suggests that there is no difference between both strategies.

Repeating this exercise for several ages, the model shows that above 35 years old female, total average treatment cost will be lower when adding PGT-A to the IVF treatment (Fig. 1).

Conclusion

According to several publications PGT-A seem to bring several advantages (1) higher pregnancy rate per transfer, (2) reduction of the miscarriage risk and (3) shorter period to baby at home. PGT-A has also some disadvantages (1) cost and (2) potential over diagnosis of aneuploid embryos.

PGT-A is a complex procedure that involves a higher level of sophistication at the IVF lab and represents a higher stress for the embryo (Munne et al., 2010; Harton et al., 2011). However, with a proper level of expertise PGT-A does not represent a threat for the embryo.

Cost is the most important barrier for patients to adopt PGT-A. Although new technologies and higher competition among genetic labs are bringing cost down, there is still a general believe that attempting to have a baby in IVF with embryo genetic screening is more expensive than without PGT-A. However, after a cost benefit analysis we have seen that PGT-A is not more expensive since its cost is balanced by the saving of additional unsuccessful transfer.

Cost-Effectiveness of Low-Cost IVF

Glossary

Clomid An oral medication used to treat infertility in women who do not ovulate.

Conventional IVF protocol Incorporates three commonly used protocols for ovarian stimulation that use higher doses of fertility medications, including agonist, antagonist, or flare and micro-flare protocols. This protocol typically requires closer patient observation given risk of OHSS, but produces a greater yield of oocytes.

Human menopausal gonadotrophins An injectable hormonally-active medication used for the treatment of infertility where they stimulate the ovaries to mature follicles, thus making women more fertile.

Intracytoplasmic sperm injection (ICSI) An IVF procedure in which a single sperm is injected directly into an egg. This procedure is typically performed in patients with defective sperm function.

Intrauterine insemination (IUI) A fertility treatment in which there is a deliberate introduction of sperm into a female's uterus or cervix for the purpose of achieving a pregnancy through in vivo fertilization by means other than sexual intercourse.

Low-cost IVF (LCIVF) A movement toward reproductive justice with primary goal of helping global infertility and access to treatment, especially in resource-poor settings.

Mild stimulation IVF Is a protocol for ovarian stimulation which is conducted in the women's natural menstrual cycle with smaller doses of stimulating fertility medications. It produces a lower yield of oocytes than the conventional stimulation protocol. Other names include mild-IVF or mini-IVF.

Natural cycle IVF No ovarian stimulatory drugs are administered and, therefore, the treatment cycle relies on the spontaneous development of one follicle production and aspiration.

Ovarian Hyperstimulation Syndrome (OHSS) A medical condition affecting women who take fertility medications which can lead to enlarged ovaries and ascites (or fluid accumulation). Most cases are mild, but rarely can be severe and/or lead to death.

'WE lab method This method utilizes simple, low cost interventions instead of expensive medical gases or high-tech incubation equipment and infrastructure typical of IVF labs in high resource settings.

The first successful pregnancy after in vitro fertilization (IVF) and the first birth from an in vitro-fertilized embryo were reported in 1976 and 1978 (Stephoe and Edwards, 1976, 1978). However despite being over 40 years since the development of IVF, the cost of treatment for patients remains significantly high. Furthermore, sophisticated technologies and expensive medications have been introduced increasing cost and limiting access despite the need. Globally, infertility is estimated to affect 48.5 million couples worldwide (Mascarenhas et al., 2012). Consequences of infertility are known to include stress, depression, low self-esteem, guilt, and marital problems including sexual problems, isolation, and abandonment. Cultural consequences include loss of legitimacy in society including inability to conduct public speaking and dismissal as a spouse (Hjelmstedt et al., 1999; Inhorn, 2003; Omurtag et al., 2009; Inhorn and Patrizio, 2015). Unfortunately, the portion of patients with infertility who seek medical care is only about half in either developed (56.1%) or developing countries (51.2%) with the percentage of patients actually receiving care substantially less at about 22.4% (Boivin et al., 2007), presumably due to limited or unavailable resources and the expensive cost (Eisenberg et al., 2010). The cost of IVF treatment is variable among different countries; however, is generally an expensive treatment. Per 2014 data, the average cost per one fresh IVF or intracytoplasmic sperm injection (ICSI) cycle was \$12.4K in the United States with Canada a close second at \$8.5K. Countries such as Australia, Brazil, Germany, Japan, Scandinavian countries, South Africa, and United Kingdom ranged from \$3–\$5K per single cycle (Collins et al., 1997; Maheshwari et al., 2009; Katz et al., 2011). With an average mean income in developed nations somewhere between \$40–\$60K, this is a significant financial cost. Comparatively, the worldwide average median annual household income is only \$10K and for those populations in third-world counties, infertility treatments may be impossible.

The majority of the costs of IVF are contributed to medication and laboratory costs, ultrasound procedures, IVF procedures (oocyte retrieval and embryo transfer), and expenditures for investigations. This does not include other extraneous costs such as charges from hospital stays, anesthesia, and administrative fees along with time lost from employment and travel costs (Collins, 2002; Wu et al., 2013).

Public funding for IVF treatment differs between countries with varying restrictions. Australia has publicly funded IVF treatment with no limitations on the number of previous cycles, maternal age, duration of subfertility, body mass index, or smoking status; however, patients are required to make expensive copayments for their treatments (Chambers et al., 2013; Harris et al., 2016). In the Netherlands, health insurance covers the performance of three IVF cycles in licensed IVF centers, irrespective of the cause of infertility. Other countries, such as the United Kingdom, provide limited public funding although with strict restrictions

(Maheshwari et al., 2009). On the contrary, the United States IVF is generally only available via private funding (Smith et al., 2011). However, in general, due to the high cost of IVF, few governments have been able or willing to subsidize IVF thereby limiting IVF primarily to the private medical sector. In patients with no infertility insurance coverage, the burden of the high fertility costs falls onto individual or couple (Collins, 2002; Spar, 2006).

Global attempts at lowering total costs of IVF emerged around 2001. Around this time, the World Health Organization (WHO) recommended that infertility be considered a global health problem (Ombelet et al., 2008). The organization aimed to increase awareness of infertility to national reproductive health education programs and services, to support the ethical acceptability of IVF, and to spread accessibility to infertility care in developing countries and other low-resource regions. In order to improve accessibility to all patients, there grew interest in exploring strategies improve the general affordability as this was deemed the largest barrier to access. In response to this announcement, the low-cost in vitro fertilization (LCIVF) initiative emerged.

LCIVF is a movement toward reproductive justice with primary goal of helping global infertility and access to treatment, especially in resource-poor settings (Ombelet et al., 2008; Hammarberg and Kirkman, 2013). The movement gained momentum in July of 2013 at the European Society of Human Reproduction and Embryology annual meeting. Willem Ombelet's nonprofit organization, The Walking Egg (WE), announced a newly invented LCIVF method based on a pilot clinical trial. The specialized LCIVF technique to that date had produced 12 healthy LCIVF babies with a total per-cycle cost as low as 200 Euros (ESHRE, 2013; Gallaher, 2013; Ombelet, 2013, 2014).

The outcomes of the WE study were based on case studies. The new LCIVF technique attempted to bypass need for a costly IVF laboratory by simplifying embryo culture methods and eliminating high-end equipment. Embryo cultures produced by the Walking Egg were simplified, low-cost and designed for easy transport (Ombelet et al., 2014; Van Blerkom et al., 2014). The method of IVF culturing is called 'WE lab method'. The method utilizes simple, low cost interventions instead of expensive medical gases or high-tech incubation equipment and infrastructure typical of IVF labs in high resource settings. The 'WE lab method' is a closed system with a connection between two test-tubes (see Fig. 1). The first tube contains inexpensive components of citric acid, sodium

Fig. 1 The tWE-lab system: (A) connection between tube 1 with citric acid and sodium bicarbonate in water and tube 2 with IVF culture medium transfers enough CO₂ gas (B) produced by the chemical reaction between the acid and the base to equilibrate the pH of the medium to ± 7.30 . Fertilization and embryo scoring by looking through the glass tube (D,E). Borrowed from Ombelet, W., J. Van Blerkom, E. Klerkx, M. Janssen, N. Dhont, G. Mestdagh, G. Nargund and R. Campo (2014). The (t)WE lab Simplified IVF Procedure: First Births after freezing/thawing. *Facts Views Vis Obgyn* 6(1): 45–49.

bicarbonate, and water and the second tube contains the IVF culture medium and the embryo. The weak acid/base combination produces and transfers enough CO_2 gas to the culture medium tube to maintain a pH of around 7.3. This closed system utilizes this simple chemical reaction to prevent adverse effects of temperature or pH changes to the culture media. The 'WE lab method initial results showed that IVF methodology could be significantly simplified and result in successful pregnancies at low cost and with easily transportable culture media (Ombelet et al., 2014).

Although this novel approach piqued interest in LCIVF, there remained some hesitations and limitations. Most importantly, given the results were based mainly on three case studies from one laboratory, the 'WE lab method needed to be replicated in different laboratories and under field conditions to assess long-term safety issues, hidden infrastructure, verify success rates, and review personal costs prior to being fully implemented. The 'WE lab method could not replicate ICSI laboratory techniques in a low-cost format. It also did not address patients who require preimplantation genetic diagnosis and screening. Therefore, the 'WE lab method is not currently an alternative option for patients requiring these more specialized treatments and testing modalities.

Another recent low cost innovation is the use of intravaginal culture (IVC) with the INVOcell™ device (Fig. 2). This device functions as an incubator for IVF embryos prior to transfer. Oocytes and sperm are cocultured in a plastic cylinder that is inserted into the vagina for 5 days to form blastocyst. This natural form of incubation replaces expensive conventional incubators that require adjustments of gas composition, temperature, pH levels, and other embryo monitoring costs. Live birth rates per cycle were similar between the INVOcell device (55%) and conventional incubators (60%). Concerns have been raised whether abnormal fertilization may go undetected due to the reduced monitoring of the developing embryos. Although further studies are necessary, the low cost of the IVC using INVOcell™ has the potential to broaden access to assisted reproduction (Doody et al., 2016).

The LCIVF movement has since expanded from beyond simplifying procedures and laboratory equipment. Current strategies focus to decrease total cost including careful patient selection, simplifying investigative methods, reducing the cost of ovarian stimulation, and minimizing the complications of IVF in both developed and underdeveloped nations (Teoh and Maheshwari, 2014).

The cost-effectiveness of IVF has also been shown to be dependent on the couple-specific chances of treatment-independent conception. The LCIVF initiative, therefore, recommends careful patient selection to avoid unnecessary interventions for patients with likely poor IVF outcomes or in patients who would be able to have similar chances of conception with expectant management. The objective is to weigh the expected probability of successful conception with treatment against the chances of conception without treatment in order to determine the most economical patient population to whom IVF should be offered. To start, the prevention of unnecessary IVF, and therefore unnecessary costs, in populations in which expectant management would lead to similar conception results has been researched. In patients with unexplained infertility without tubal pathology or severe male-factor infertility, the natural conception rate can be >50% if expectant management is adopted (Custers et al., 2011; Kamphuis et al., 2014).

Fig. 2 The INVOcell™ utilizes the vagina as a natural form of incubation to support fertilization and embryo development prior to transfer. Borrowed from invobioscience.com.

Economic-modeling studies also reveal that in unexplained infertility in younger women, IVF treatment may not be cost effective within 3 years of trying to conceive. And in women >35 years of age with primary infertility, immediate IVF is more cost-effective than delay of IVF (Mol et al., 2000; Kamphuis et al., 2014). In Canada, where IVF is publicly funded without age limits, a study in 2015 supported the need for age eligibility criteria as the cost of fertility treatments significantly increased over the age 40 with low live birth rates. The study results noted that the mean treatment cost per birth (excluding medications) for a 40 year old was \$43,153 with live birth number of 105 compared to a 44 year old where total cost was \$597,800 with 0 live births (Ouhilal et al., 2015). Other studies address infertility type along with ideal treatment modality approach. Many patients may be candidates for less expensive options for fertility treatment including use of ovulation induction and/or intrauterine insemination (IUI). For instance in women with patent fallopian tubes, proceeding with IUI with/without clomid or human menopausal gonadotrophins (hMG) before IVF is more cost effective. However in women with blocked fallopian tubes, IVF-Embryo Transfer appears to be the most cost-effective modality and, therefore, no cost or time should be wasted proceeding with initial IUI attempts (Van Voorhis et al., 1997). Therefore, the overarching belief behind careful patient selection is to identify which patients are most ideal candidates for IVF—based on age, infertility type diagnosis, and timing of treatment—to provide the most cost-effective treatment approach.

Another method for limiting expenditures targets the simplification of baseline investigations and equipment use in the laboratory. The goal is to limit duplicated or unnecessary studies and to proceed with the most inexpensive option first. Studies have shown that practices involved in investigation of infertility are widely variable among developed counties and even among various practices in similar regions (Helmerhorst et al., 1995; Ojha et al., 2003). These differing investigation protocols can lead to significant differences in the cost of baseline investigations. The LCIVF initiative moves to have standardized protocols that focus on inexpensive, but adequate, baseline investigations for infertility. Firstly, male-factor fertility can compose up to 40% of infertility diagnoses in couples and initial evaluation with semen analysis is one of the most inexpensive costs that should be performed early in the investigation of couple infertility. An adequate history, pelvic examination, and pelvic ultrasound with antral follicle count (AFC) are also inexpensive assessments that are recommended. Ovarian reserve testing utilizes biomarkers and imaging techniques to determine the quantity of oocytes capable of fertilization. The goal of ovarian reserve testing is to assess reproductive potential and to predict an individual's response to ovulation induction agents. The most common biomarkers include basal follicle-stimulating hormone (FSH) plus estradiol levels or anti-Müllerian hormone (AMH). The cost per live birth was greatly reduced when ovarian reserve testing was used in comparison with initiating IVF treatment without any information of ovarian reserve. In addition, inducing ovarian stimulation without the predictive value of ovarian reserve can be dangerous given risk of ovarian hyperstimulation syndrome (OHSS) (Nardo et al., 2011). No single assessment of ovarian reserve has 100% sensitivity and specificity and, therefore, tests often are combined in an attempt to improve the prediction of poor outcomes. However, models of combined ovarian reserve tests do not significantly improve the ability to predict poor reproductive outcomes over single ovarian reserve tests (Practice Committee of the American Society for Reproductive, 2015). Furthermore, the use of multiple ovarian reserve tests may complicate the understanding of an individual's ovarian reserve and increase the expense of screening.

The value of using specific imaging techniques is more difficult to standardize as costs, availability, and treatment protocols differ in varying regions. For instance, in places like the United Kingdom where IVF is considered the most cost-effective treatment for all subfertility factors apart from anovulation, assessment of tubal patency and/or hysteroscopy may not be necessary as they will not affect treatment route (National Collaborating Centre for Women's and Children's Health (UK), 2013). And although laparoscopy is the goal standard for diagnosis of tubal patency, use of other imaging modalities prior including HSG and SIS are less expensive and less invasive options which should be considered anywhere that these are available. Options such as office endoscopes may be more beneficial in the near future as use prevents need for costly operating room expenditures.

The next step at expenditure reduction explores ovarian stimulation and medication costs. Movements at reducing costs of ovarian stimulation and medication costs have transitioned to natural cycle or mild stimulation protocol (or "mini-IVF") rather than conventional stimulation (Teoh and Maheshwari, 2014). The overall purposes are to reduce costs of medications, treatment invasiveness, and complications. In natural cycle IVF, no ovarian stimulatory drugs are administered and, therefore, the treatment cycle relies on the spontaneous development of one follicle production and aspiration. The cumulative probability of pregnancy is 46% with a live birth rate of 32% after four cycles of treatment (Nargund et al., 2001). Mild stimulation procedures have also been utilized which use low dose gonadotropins. Both the natural cycle and mild stimulation cycle IVF are significantly lower cost than conventional IVF by at least \$5K (Siristatidis et al., 2012; Crawford et al., 2016). Other clinical benefits include shorter duration of the protocol, simplicity of treatments/follow up, and reduced patient discomfort. Due to less follicular development, there are fewer required monitoring visits, including transvaginal ultrasound examinations and blood tests, than conventional IVF. Likewise, with use of lower dose or no gonadotropins, there is decreased risk of OHSS that can cause significant morbidity and potentially high costs for treatment. However, due to low ovarian response with subsequent high cancellation rate, the current evidence does not favor natural cycle or mild stimulation IVF (Pelinck et al., 2002; Ombelet et al., 2008). Natural cycle and mild stimulation IVF may prove costlier than conventional IVF in the long run due to the lower live birth rate per cycle and, therefore, overall need for more treatment cycles (Groen et al., 2013; Crawford et al., 2016). Another disadvantage of natural cycle and mild stimulation is the lower number of oocytes retrieved and, subsequently, the inability to store unused embryos. Thereby, this increases the number of necessary cycles along with the potential morbidity associated with oocyte retrievals. Natural cycle or mild stimulation protocols may be advantageous for select patient populations; however, full disclosure regarding potential benefits and risks, including lower per cycle birth rates, must be performed. Additional randomized control trials comparing natural cycle, mild stimulation, and conventional IVF may help clarify the ideal patient populations for each method.

Lastly, the LCIVF initiative directs attention to optimizing the safety of infertility treatments and minimizing the complications, especially OHSS and multiple pregnancies. As mentioned above, OHSS can be expensive to treat, however, more importantly can endanger the life of the patient. The moderate and severe forms of OHSS are typically treated in an inpatient setting and put patients at risk for complications such as hypovolemia, respiratory/circulatory shock, ovarian torsion, ovarian rupture, thrombophlebitis, and renal insufficiency. Aspiration of accumulated fluid from the abdominal and/or pleural cavities may also be necessary, thereby requiring input and assistance from a multidisciplinary team (Joint Society of Gynecologists of Canada-Canadian Fertility Andrology Society Clinical Practice Guidelines et al., 2011). The use of natural cycle and mild stimulation has been believed to help reduce incidence of OHSS due to the lower dose of fertility medications (Williams et al., 2002; Aboulghar and Mansour, 2003). Regarding multiple gestations, over the last 30 years there has been a 65% increase in the frequency of twins and a 500% increase in triplet and higher-order births, primarily due to the increased use of assisted reproductive technology. These multifetal births account for a high incidence of perinatal morbidity and mortality, including complications such as preeclampsia, preterm labor, preterm rupture of membranes, placental abruption, pyelonephritis, and postpartum hemorrhage (Cunningham et al., 2010; American College of Gynecologists Committee on Practice et al., 2004). In comparison to singletons, multi-fetal gestations are at least six times more likely to develop cerebral palsy (Pharoah and Cooke, 1996). In 2014, the costs associated with perinatal morbidity for IVF multiple gestations in the United States were estimated at \$6.3 billion (Allen et al., 2014). In the United Kingdom, it has been shown that 56% of the direct cost of IVF pregnancies is associated with multiple gestations after IVF (Ledger et al., 2006). Therefore, the practice of single-embryo transfer has been encouraged as it has shown to drastically reduce the incidence of multiple pregnancies (Ombelet et al., 2008; McLernon et al., 2010).

The various LCIVF initiatives hold great promise, especially to resource-poor regions and nations. However, the techniques and strategies are still in the formative stages. The advantages of current LCIVF advances include focusing on appropriate patient populations and treatment timing, shortening of stimulation time and medication cost, decreasing laboratory costs, and reducing chances of, and therefore morbidity associated with, OHSS and multiple pregnancies. It pushes for low-cost medication through different ovarian stimulation protocols, although with a disclaimer to patients regarding decreased life birth rate per cycle. The most significant breakthrough in cost-reduction is the invention of a simplified culture system (the 'WE lab method), which can reduce the laboratory cost up to 90%. LCIVF and the simplified culture system can be promising to patients, especially in resource-poor countries who may otherwise receive no treatment. Nonetheless, these LCIVF initiatives come with certain limitations. In developed countries, high-tech treatment programs/laboratories and easily available resources are already established and have been clinically validated and study-proven. Additionally, the implementation of age-limitations to infertility treatment comes at a psychological cost to reproductive liberties. The danger of low-cost IVF may also mean low quality of care or need for repeat cycles that in turn become more expensive.

Overall, the trend for the development of low-cost IVF is encouraging, especially to those who are financially disadvantaged or in underdeveloped nations. Further research is needed to decide the clinical and cost effectiveness of these initiatives on a larger scale. In an ideal world, cost should not be the main barrier to parenthood.

THE SUPPORT TEAM

Patient Support in the ART Program

Sharon N Covington, Shady Grove Fertility, Rockville, MD, United States

Overview

Infertility is a life crisis as old as time. Despite the mind-boggling technological advances in the diagnosis and treatment of impaired fertility, the one element that has remained constant is the profound emotional response a person or couple usually experiences when their desire to have a baby is thwarted. The psychic conflict produces an amalgamation of emotions related to loss and grief, as well as stress and distress, which is well documented throughout the literature (Covington and Burns, 2006).

The psychological understanding of infertility has shifted over the years with the growth of patient advocacy and evidence based approaches to care. In the early to mid-1900's, when no medical reason could be found for infertility, it was proposed that patient psychopathology was the etiological factor. This psychogenic model of infertility prevailed until the late 1970's when a shift occurred, partially through the advocacy work of Barbara Eck Menning, formulating that emotional distress is the consequence and not a cause of infertility (Covington and Burns, 2006). The psychological sequelae model identified numerous psychological factors, affecting all aspects of an individual's and couple's life, which result from infertility. The application of this model has led away from the individualistic perspective of the psychogenic model to a more holistic approach whereby interactions among individuals/couples and social/medical components must be factored into medical treatment. Further developments emerged with extensively reviewed research on the negative impact of infertility and its treatment on the well-being of patients that has resulted in the development of evidence-based interventions to support coping and resiliency (Boivin and Gameiro, 2015).

Assisted reproductive techniques (ARTs), while opening up expanded opportunities for the treatment of infertility, have generated their own psychological challenges for patients. For most couples, ARTs are the last, best option for having a child, often occurring after long months, and sometimes years, of treatment failure, and typically at tremendous emotional, physical, and financial cost. Patients entering ART programs usually do so with the burden of grief and disappointment from infertility, acting depressed, angry, tired, dependent, and anxious. Although emotionally depleted, couples are attracted to a technology that offers hope where, not so long ago, none existed. They find themselves drawn into a new emotional turbulence of contrasting feelings of hope and despair, which seem to be generated in part by the experience of the technology itself. The intensity and high-tech nature of ART create a stressful atmosphere, where the stakes are high and the chance of success may be relatively low.

There is an increasing awareness of the burden of infertility treatment, especially in the ART program. Issues related to psychological strain and distress, poor interactions between patient and clinic staff, and the physical drain of treatment itself are all considered to be reasons for discontinuation from medical assistance. When factored together, the single biggest reason for ending treatment before having a child, is not related to money or time, but rather the emotional cost of treatment and its affect has on one's life (Gameiro et al., 2012). Thus, identifying ways to reduce the emotional burden of treatment and provide better supportive care is fundamental in any ART program, with the goal being delivering good care and positive treatment outcome (Boivin et al., 2012). The recognition of treatment burdens has resulted in a growing consensus among all reproductive medical organizations that patients seeking assistance need a "patient-centered" approach, care that is focused on individual patient needs, while being responsive and respectful to patient preferences and values (Van Emple et al., 2011). Patient-centeredness is considered a core construct in quality medical care. Taking a patient-centered approach, this section will focus on providing support in the ART program by identifying levels of psychosocial care, types of services offered, and how best to provide access to resources.

Levels of Support Care

As noted, given the substantial research on the emotional consequences of infertility and ART treatment, it is clear that patients need psychological support as an integrated part of the medical treatment process. "Who is to provide the care?" is sometimes the question. As reproductive technology has advanced, so has the role of mental health professionals (MHPs), which include social workers, psychologists, psychiatrists, marriage and family therapists, licensed professional counselors, and psychiatric nurses, as important members of the reproductive medical team (Boivin and Gameiro, 2015). The specialization of "[in]fertility counseling" has evolved internationally, combining the areas of reproductive health psychology and reproductive medicine, providing skilled psychosocial care in all phases of treatment. The phrase "infertility counseling" itself has shifted over time to "fertility counseling" reflecting more positive terminology and broader reproductive health perspective regarding treatment of patients who may not be technically infertile (i.e., lesbian, gay, single, etc.) (Covington, 2015). Fertility counselors serve as a resource to patients and staff by providing specialized psychological services that support and enhance quality care. For example, the complex medical and

psychological issues in third-party reproduction have social and legal implications that must be assessed carefully, and warrant involvement of a qualified MHP experienced in fertility counseling. As part of patient preparation, the implications and psychosocial impact on the off-spring created by third-party reproduction must be considered, and assistance given to families dealing with these issues pre- and posttreatment.

Nevertheless, the responsibility for patient support in the ART program is the duty of all staff members, not just the domain of nurses or fertility counselors. Interactions with each staff member, from administrative to physician, influence a patient's perception of care and, in turn, his or her stress level. Good communication with sensitivity, warmth, patience, and responsiveness create an environment of support. Also, the general clinic routine and ambience reflect support and respect of patients when it is provided in an efficient, organized, clean, uncrowded, and esthetically pleasing atmosphere. All staff need to be sensitive to and knowledgeable about the psychological needs and stresses of ART patients (Gameiro et al., 2013). While the primary focus of physicians, nurses, laboratory scientists, and other healthcare staff is the medical diagnosis and treatment of infertility, it must also entail "treating the patient, not the disease", thus necessitating a patient-centered approach.

Routine Versus Specialized Care

Taking an evidence-based method, the European Society of Human Reproduction and Embryology (ESHRE) published extensive guidelines for routine psychosocial care for fertility staff (Gameiro et al., 2015). Underscoring the word "routine", the Guidelines state that psychosocial care must be the responsibility of all staff members with patient contact, and occur across the treatment spectrum from the beginning when the diagnosis process is started, throughout treatment phases, and at the end of treatment particularly when it is not successful. Routine care includes providing information, resources, self-help support tools and interventions, as well as overall positive clinic environment. Four domains of care are identified according to patient needs: behavioral (life style, nutrition, exercise, and compliance); relational (partner relationships, family, friends, and social network); emotional (anxiety, depression, quality of life and well-being); and cognitive (understanding of treatment, concerns, and knowledge). Specific recommendations are given on patient needs, identified as conditions necessary for a healthy experience, on these four domains all of which are supported by an extensive review of the literature.

While routine psychosocial care is the responsibility of all reproductive clinic staff in providing patient support, specialized psychosocial care must be provided by qualified MHPs trained in fertility counseling and psychotherapy. Despite the stressful consequences of infertility and ART, numerous studies have shown that the clear majority of patients are well adjusted, psychologically resilient and maintain adequate social function. For the roughly 20% of patients who are at risk of clinically significant emotional problems (Verhaak et al., 2010), psychosocial services should be provided trained fertility counselors ideally integrated in as part of the clinic staff (Covington and Burns, 2006; Covington, 2015). Specialized patient support services provided by trained fertility counselors may include psychosocial assessment and evaluation; implications, supportive and therapeutic counseling; and psychoeducational counseling.

Types of Support Services

ART patient support services are as routine as overall clinic administration, communication, and environment to specific specialized psychological services involving psychoeducation, assessment and psychosocial intervention. From the routine to the specialized, the methods of providing patient support services will be categorized for this discussion as clinic management; information and education; assessment; therapeutic counseling; and supportive counseling (see Fig. 1).

Clinic Management

The approach in which a clinic is managed, along with physical setting, is an essential aspect of patient support and a means of promoting better quality of care. Interactions between staff and patients as well as the overall environment of clinic operations impact patients on the most basic of levels—patients' stress levels, perception of care and emotions. In a systematic review of patient satisfaction studies, Dance et al., identified that clinic factors were significant in care and problematic in that the level of satisfaction was low (Dancet et al., 2010). Physical comfort was important as well as other factors such a caring relationship (good attitude, sensitivity, trustworthiness, etc.) and good technical skills (high quality information, counseling, best medical options, and comprehensive testing and treatments) provided by competent staff. Unfortunately, the consensus from the study reviews were that patients viewed clinic factors as greatly lacking.

Staff interpersonal skills that enhance good communication, empathy, and respect are a fundamental aspect of patient support, yet may be often overlooked or minimized. Simple interactions that personalize care, such as introducing oneself, identifying the reason for appointment, giving information about procedures, looking patients in the eye and asking about concerns provide patient support. Classes in effective communication are a means of training staff in skills that are as important as their clinical abilities, and should be offered to all staff with patient contact. Often staff feel inadequately trained to deal with difficult patient situations, from complaints, delivering bad news, to strong emotions. In addition, helping staff "find the right words" in various contexts of patient care can be very effective in helping patients deal with the burdens of treatment (Boivin et al., 2012).

Fig. 1 Types of support services.

Communication training can also potentially help with staff turnover, as it can provide skills in dealing with difficult situations that may lead to compassion fatigue and burnout.

Clinic management should also consider the physical burden of treatment on patients and how protocols and procedures might be adjusted to lessen them. For some patients, the physical demands of treatment are more difficult to deal with than the emotional. Bodies being poked, prodded, and punctured with needles, instruments, medications, and intrusive procedures (often by people patients view as total strangers) are depleting, exhausting and painful. Considering medications and protocols that may be less invasive and physically disruptive, while allowing patients to participate in decision-making can be helpful. Boivin and colleagues reviewed a number of interventions which target treatment and clinic management demonstrated to be effective in patient centered care (Boivin et al., 2012). In addition, tools are now available to help clinics reliably survey their patient's experiences with focused fertility care. The Patient Centeredness Questionnaire-Infertility (PCQ-infertility) measures patient's particular experiences, rather than overall satisfaction, and thus can be tailored to improving clinic specific care (Van Emple et al., 2011). Reviewing periodically with such a tool can help clinics make adjustments to care and environment that are focused on patient needs and which encourage compliance with treatment.

Information and Education

Probably the most far-reaching opportunity for ART support is through patients' easy access to written information and education about the medical and psychological aspects of infertility. Patients rely heavily on the educational materials that document the process and procedure of ART, and search out information at the clinic, through the media (TV, magazines, books, etc.), and on the internet. Patients often identified informational materials as a primary source of support, after talking with spouse, family, or friends, and thus need assistance in accessing reliable and accurate information on their care and condition. The American Society of Reproductive Medicine (ASRM) has a section devoted to patient education, fact sheets, and educational videos that cover a wide range of reproductive health topics (www.reproductivefacts.org). Patient advocacy groups, such as RESOLVE (www.resolve.org), also have an abundance of information and resources on infertility and family building options. In addition, excellent material for patients who have or are using donor assistance in creating a family is available through the Victorian Assisted Reproductive Treatment Authority (www.varta.org.au) as well as other advocacy groups, such as the Donor Conception Network (www.dcnetwork.org).

Any information and treatment packets sent out to new patients should include material on the emotional aspects of infertility and on support resources available through the clinic, in the community, and via the Internet. For example, men are sometime forgotten in educational materials, particularly on coping, and a two-page booklet helping men prepare for a fertility workup, could be considered in these materials (Pook and Krause, 2005). A clinic's website is also an important source of support information and could connect to other internet resources, articles, advocacy groups, etc. for easy patient access.

Another area of education occurs in services that increase involvement with patients' overall health and well-being. A clinic may want to consider offering a "wellness program" that includes resources to enhance coping during treatment including acupuncture and yoga. In addition, nutritional programs that help patients address weight issues which can impact fertility treatment is often a needed area of support and intervention. At the very least, clinics need to identify referral sources within the nearby community and provide patients with written materials on where they can find sound professionals who provide services in these areas.

Assessment

The shift to patient centeredness has resulted in the development of a several psychosocial tools available to help identify patients' at risk for distress at the start of medical evaluation. Every patient brings a psychological history to infertility and some, as a result, may be more vulnerable to the experience. Being able to identify patients at risk before treatment begins (as well as during treatment) can assist in providing support and therapeutic interventions that will help in their care and the ability to comply with treatment. SCREENIVF is a validated, self-administered tool that provides specific information on those at risk, including a patient's vulnerability to depression, anxiety, fertility cognitions, and need for social support (Verhaak et al., 2010). The Fertility Quality of Life (FertiQoL) measures treatment quality (interactions with staff and quality of information) and treatment tolerability (effects on mood and disruptions to daily life), and proves to be an invaluable tool for clinicians. It is completed on line (with results sent to the clinician), currently available in 31 languages, and takes about 10–15 min to complete (www.fertiquol.org) (Boivin et al., 2011). Both these tools are at no cost. While there are a number of other validated, general self-screening inventories for depression and anxiety, the tools mentioned are specific to the infertility and its treatment.

Therapeutic Counseling

Another aspect of patient support services involves specialized intervention and treatment care for the consequences of infertility, or for underlying psychological disturbances that could affect medical treatment. Fertility counselors can provide treatment modalities of individual, couple, and group counseling to assist patients in understanding and handling the emotional sequelae of infertility; identifying and developing coping mechanisms to deal with treatment; managing the effects of infertility or psychosocial history on interpersonal functioning (anxiety, depression, etc.) and on marital, sexual, and social relationships; considering the implications of ART treatment; decision-making on treatment options and alternative family building; pregnancy and parenting following treatment; and ending treatment and building a life after infertility. Appropriate mental health referral sources for psychotherapy should be made available for patients with pre-existing emotional problems and those issues exacerbated by treatment. Unfortunately, research has found that while some patients experience significant symptoms of depression and anxiety, most do not receive referral for appropriate mental health services (Pasch et al., 2016).

Group counseling has been shown to be a highly effective, cost efficient intervention for producing positive change, particularly when education and skills training (e.g., relaxation techniques) are emphasized. Regular support group meetings, offered in the clinic and facilitated by a fertility counselor, help with the emotional isolation patients often feel with infertility. These groups can also provide a forum for learning coping strategies which ultimately allow patients to continue with treatment (Covington and Burns, 2006). As an example, groups can be an effective way to help patients change unhealthy behaviors (smoking, overweight, etc.) which effect treatment, though psychoeducation and peer support. In addition, groups can be used to prepare and educate patients about third-party reproduction, when required for treatment, and help “normalize” the experience in a way that individual or couple counseling cannot.

Supportive Counseling

Supportive counseling involves reproductive healthcare providers giving both advice (counsel) and comfort (console) to patients. Nurses often assume primary responsibility for patient support, yet all members of the treatment team have opportunities for advising and consoling. To begin, clear information needs to be provided to patients on what services are available and how they can access psychosocial support, whether through the clinic or outside resources. This information should be clearly displayed and included on all materials distributed to patients. Information on patient advocacy groups, such as RESOLVE, which offer peer support forums and web-based resources should also be included.

Patients need to be educated and offered easy tools to help in coping with treatment. These tools are self-administered and require minimal explanations from clinic staff to use. The two-week waiting period before a pregnancy test has been shown to be one of the most difficult times during the treatment cycle. The Positive Reappraisal Coping Intervention (PRCI) helps patients work on reappraising aspects of the infertility experience in a more positive way (possible benefits rather than focusing on the costs) which help to change feelings (Lancastle and Boivin, 2008). The PRCI is also helpful during other times of uncertainty, such as with patients experiencing recurrent miscarriage, and can be used throughout the day when anxiety or negative thoughts take over. The information can be placed on a card for easy use. In addition, a number of apps for android phones help patients with an array of mind-body techniques related to breathing, mediation, graduated relaxation, guided imagery, etc. *FertiCalm*, designed by two reproductive health psychologists, specifically targets the many aspects of infertility treatments with cognitive-behavioral techniques for coping.

Access to Resources

Support services can be delivered in the “here and now” of clinic interactions, operations, and on-site counseling as well as in the “virtual” reality of computer mediated technology. To begin, a clinic's website reflects the practice's patient centeredness and is an important source of medical and support information. Articles, blogs, seminars and webinars, and resource information help to

educate patients and convey a message about clinic philosophy in patient care. Many clinics now have Facebook pages for their patients to connect on a variety of infertility related topics (i.e., single women, PCOS, pregnancy loss, etc.). The clinic website serves an introduction to the practice and can serve as a springboard to connecting patients to other reliable internet sites for medical and psychosocial information.

Computer-based technology has become a powerful source of information and emotional support for patients. A scoping review of patient-focused internet based intervention studies in fertility care found a number of multimedia, interactive formats being applied for support, education, and promoting mental health (Aarts et al., 2012). Thus, the internet can provide an effective forum for intervention in helping patients manage the distress of infertility, yet receiving direction from the medical staff on reliable Internet sites for information is needed. Social media, such as Facebook and Twitter, have become resources for support, interaction, and information for infertile patients when managed by the clinic, as well as providing a marketing tool for the practice. Finally, providing Internet access to personal health records and medical data is increasingly being considered within reproductive clinics to improve patient empowerment and satisfaction with care (Van Empe et al., 2011).

When possible, clinics should have a trained MHP on-site to offer easy access to patients for specialized psychosocial care of individual, couple and group counseling. A clinic fertility counselor, also, has the ability to help in staff training on effective communication as well as managing staff stress levels which can lead to burnout and turnover. At the very least, clinics should have a list of trusted fertility counselors as referral sources for patients, and all counseling resources should be easily accessed within the clinic and on their website.

The increasing use of telehealth in patient care as well as the reality that patients may be traveling great distances for treatment, presents the opportunity to provide counseling and patient support via secure teleconferencing platforms. It is important to have staff who are competent and comfortable in using teleconferencing. While a number of servers exist that are HIPAA compliant, it is imperative for patients to understand that security and confidentiality cannot be completely ensure when using any internet-based technology. No doubt, the field of telehealth will continue to evolve and offer more opportunities for patients to receive support wherever they are located, while requiring clinics (and staff) to be current and proficient in these technologies.

Table 1 Support strategies across treatment

Before

- Educational classes presented by each member of the treatment team on IVF
- Pretreatment assessment tools (i.e., SCREENIVF and FertiQol)
- Pretreatment counseling session with an fertility counselor
- Psychosocial preparation and assessment of gamete donors, recipients, and surrogates with a fertility counselor
- Extensive written materials available and distributed on the medical, emotional, and financial aspects of ART
- Educational videos on the medical and emotional aspects of infertility and ART
- Support groups
- Educational and support materials available on clinic website, including podcasts, webinars, and social media outlets
- Stress management, relaxation, and guided imagery classes
- Resource lists of community support services including RESOLVE, Inc.

During

- Access to a fertility counselor and other team members
- Telephone support with a primary-care nurse
- If a patient has met with a fertility counselor before starting the cycle, a brief visit in the OR on retrieval and/or transfer day
- Stress management, relaxation, and guided imagery classes
- Complementary programs such as acupuncture, yoga, and nutrition counseling
- Coping materials for the two week wait or during times of uncertainty (i.e., PRCI)
- Computer-mediated technology, including clinic website with resource materials and interactive social media (e.g., Facebook and Twitter); online educational webinars, written materials identifying reliable Internet sites for information and support, and android phone Apps supporting coping techniques (i.e., FertiCalm)
- Support groups

After

- Psychosocial follow-up after a failed cycle or pregnancy loss
- Decision-making counseling regarding alternative therapies or ending treatment
- Counseling on alternative family building through adoption or third-party reproduction
- Counseling and support for the decision to remain child-free after infertility
- Counseling and preparation for multiple pregnancy, including selective reduction
- Counseling and follow-up for pregnancy after infertility, including support groups
- Counseling and follow-up for issues in parenting after infertility, including families created through donor gametes
- Support groups
- Patient feedback survey (i.e., PCQ-infertility)

Conclusion

Patient support is the responsibility of all who work in an ART program. Infertility is an emotionally exhausting, psychologically demanding experience for patients and, at times, their caregivers. Since ART is considered the most stressful of all infertility treatments, patients who undergo it need as much support psychologically as they do medically from their clinical team. It can begin before a patient steps through the door of a clinic requesting evaluation and may continue after the patient ends treatment, whether pregnant or not.

Table 1 identifies strategies which will assist practices in providing patient support services across the treatment spectrum. Integrating in these services as part of patient care and training all staff to be sensitive to the emotional needs of infertility patients will help to minimize the burdens of ART treatment, thus offering the best opportunity for helping patients achieve their goals in family building.

Introduction

Infertility is commonly misconstrued as a purely physiological issue, having little to do with the psychological state of the patient or her partner. While the primary doctors in charge of infertility are the obstetrician/gynecologist and the reproductive endocrinologist, the mental health professional (MHP) also plays a pivotal role in the world of infertility. MHPs are under-utilized by most infertility centers, with their role being restricted to just third party evaluations (third party referring to egg donation, sperm donation, gestational surrogacy, and/or embryo donation) in some centers. However, MHPs can and are a highly effective member of the infertility care team through patient interventions that decrease stress, which can lower the emotional burden for patients as well as potentially decreasing dropout rates and increasing pregnancy rates. In addition, being a nurse or other caregiver for couples struggling with infertility can lead to burnout and depression; providing mental health services to nurses may improve the infertility experience for patients and reduce nursing turnover due to burnout. Finally, the MHP can provide training in empathic skills communication to the entire medical team, including physicians, which could also lead to a lower burden of care in patients.

The role of the MHP in the infertility setting has changed dramatically over the past few decades. The “pioneer” practitioners focused on counseling by conducting psychoeducational sessions for patients facing treatment, identifying which patients expressed the most distress and offering therapy sessions in an effort to relieve at least some of that distress. They also educated the medical community that infertility patient care needed to focus on the whole patient, not just the physical aspects of the diagnostic workup and subsequent treatment.

Currently, most MHPs who specialize in reproductive medicine dedicate all or most of their time to third party patients. The American Society for Reproductive Medicine (ASRM) guidelines include recommendations or requirements that individuals and couples who are pursuing egg or sperm donation, surrogacy, or embryo donation receive counseling. Thus, many MHPs do not have the availability to see non-third party patients and/or the medical team does not think to refer them for counseling. This model of care does not benefit the vast majority of infertility patients or the health care team. The MHP needs to hold a more vital role in the care of our patients in order to improve the treatment experience, potentially increase fertility rates, as well as leading to decreases in dropout rates.

Stress in Infertility

The current research on mental health disorders in infertile women, as well as couples, is consistent and clear; women and men experiencing infertility report heightened levels of anxiety and/or depression. In fact, patients struggling with infertility have similar levels of anxiety and depression as patients with cancer, heart disease, or HIV positive status (Domar et al., 1993).

In a gold-standard study which utilized a structured psychiatric interview instead of a self-report questionnaire (in which many patients may “fake good” in order to appear able to handle treatment), women visiting a fertility center for the first time met with a psychiatrist. Of the 112 participants, 40% were diagnosed with a psychiatric disorder, the most common being anxiety and depression (Chen et al., 2004). In a larger study of IVF patients, utilizing a self-reported psychiatric questionnaire, 31% of females and 10% of males had a psychiatric diagnosis: depression, anxiety or both (Volgsten et al., 2008). The study also determined that most of the patients with the psychiatric disorders were undiagnosed and untreated, with only 21% receiving any treatment.

In regards to suicide risk, a study on 106 women presenting at an infertility clinic found that 9% of women reported having suicidal thoughts or attempts; women who had no or fewer children and had higher levels of depressive symptoms were most likely to report suicidal symptoms (Shani et al., 2016). Researchers suggest that infertility patients may also display symptoms of obsessive-compulsive disorder, psychoticism, and battle with substance abuse and eating disorders (De Berardis et al., 2014).

Stress and Treatment Termination

Until a series of studies was published in 2004, it was assumed that patients dropped out of treatment for only two reasons—either they didn’t have the money to undergo further treatment, or their physician recommended that they discontinue treatment due to a poor prognosis (called active censoring). In fact, finances are the most common reason for treatment termination in uninsured patients. However, recent research consistently demonstrates that the emotional burden of treatment is the most common reason given by insured patients who drop out of treatment.

Patient drop out is an issue worldwide. In the Netherlands, 32% of patients dropped out before completing three cycles, in Germany 39% dropped out after the first cycle, and in France more than a third dropped out after only one cycle (Troude et al., 2014). In Israel, couples are offered unlimited free IVF until they have two children, and their centers also experience patient

dropouts. A cohort-study showed that the main reasons for treatment termination in a cost-free environment like Israel were psychological burden and lost hope of success (Lande et al., 2015). In our most recent study, we surveyed 268 women who had insurance coverage for six IVF cycles but did not complete them, nor did they achieve a pregnancy. The most prevalent reason for discontinued treatment was that it was too stressful (41%) (Domar et al., 2016), which aligned with our prior research showing 39% dropped out due to stress (Domar et al., 2010).

There are many factors associated with treatment termination, including depressive symptoms prior to the first cycle, biochemical pregnancy or miscarriage from a previous cycle, older age, perception of poor prognosis, lost hope for success, and minimal family support. In order to decrease patient burden, Boivin et al. (2012) created a list of recommendations to support infertility patients undergoing IVF treatment. These include tailored educational materials, checklists to make sure all treatment worries are addressed, screening high risk patients for psychological issues, and implementing coping interventions for patients. It is also recommended to refer high risk patients for emotional support with a MHP who specializes in reproductive medicine, and to ensure that the partner is involved.

In general, the research suggests that the emotional and psychological needs of our patients are not being met. In a recent study of men and women undergoing IVF (Pasch et al., 2016), 57% of women and 32% of men reported depressive symptoms and 76% and 61% respectively reported symptoms of anxiety. Of the patients displaying psychiatric symptoms, only 21% of women and 11% of men reported that they had received mental health services; about 25% of participants stated that the fertility clinic had made information on mental health services available to them. The men and women who had reported significant depressive and/or anxiety symptoms, even those with a prolonged history of symptoms, were no more likely than other patients to have received information about mental health services. The authors concluded that emotional distress is common, most patients don't receive mental health services information or referrals, and most importantly, there is no targeted approach for those most in need.

Psychological Interventions for Infertility Patients

There have been numerous randomized controlled studies on the efficacy of psychological interventions for infertility patients. There are at least three meta-analyses which summarize the data. In the first (Boivin, 2003), the psychological interventions which were identified as being the most effective in reducing psychological distress were those which included specific coping strategies for reducing distress. In the second (Hammerli et al., 2009), the interventions which were identified as being the most effective were group sessions of at least six sessions. Finally, a recent meta-analysis (Frederiksen et al., 2015), indicated that psychological interventions which had a cognitive-behavioral therapy (CBT) focus were the most effective. Thus, if one combines the results of the three meta-analyses, a group intervention of at least six sessions, with focused coping strategy acquisition based on CBT should provide the best relief to women struggling with infertility.

The Mind/Body Program for Infertility was first launched in 1987 and there have been a number of RCT's to examine its effectiveness (Domar et al., 2000a,b, 2011). The 10-week group program includes relaxation exercises, cognitive strategies, lifestyle modification, as well as group support. Research indicates that participants experience significant reductions in psychological distress, stress-related physical symptoms such as insomnia and headaches, as well as increases in pregnancy rates. The clinical program is currently offered at numerous centers throughout the US, as well as internationally. Participants report improvements in all symptoms and approximately 55% conceive within 6 months.

Nursing Burnout Prevention

Another critical role of the MHP in the infertility clinic setting is in preventing nursing burnout. Burnout occurs when one feels overwhelmed by extreme prolonged stress. Many nurses begin to experience burnout as the stress of their job increases, and they then experience lower levels of motivation and dedication to their patients. In fact, prior findings suggest nurses leave their job or abandon the practice of nursing all together as a result (Constable and Russell, 1986).

Previous research suggests that the factors contributing to nursing burnout are due to low job enhancement, work pressure, and lack of supervisor support (Constable and Russell, 1986). In a survey of more than 700 nurses, it was determined that those who were motivated primarily by the desire to help others, rather than by enjoyment of the work, were more likely to burnout (Dill et al., 2016). Unfortunately, the characteristics that one looks for in a REI nurse—a deep sense of commitment and compassion, as well as being extremely detail-oriented—are also characteristics associated with the development of burnout.

In a 2016 survey of ART clinic nurses performed by ASRM, 80% reported that their workload had increased in the past year, more than 70% reported that their stress level had increased, 60%–70% reported that patient expectations/demands were the main contributors to nursing stress, and more than 70% had experienced burnout in their job setting (Tobias, 2016).

A survey from the European Society for Human Reproduction and Embryology (ESHRE) on staff burnout had similar findings (Boivin et al., 2017). The survey focused on three topics: work stressors, perceived sources of difficulties and understanding what, if any, workshops clinic staff be willing to attend. The findings of this survey concluded that time pressures, workload, and team management issues were among the top work stressors, while patients' unrealistic expectations, communication and counseling patients added to their stress. Survey respondents reported they felt they had to prioritize tasks from clinical duties and

administrative duties and did not have time to complete both to the fullest during the work day. Sadly, it was noted that there is not enough time to counsel patients and give them the attention and care they may need. As we know, infertile patients experience much distress during treatment, so referrals to a MHP are of even more importance since other staff may not be able to provide adequate attention to the patient's psychological needs.

Given the scope of infertility treatment, nurses are often presented with the burden of telling patients of a negative outcome. Having to share bad news on a regular basis can be emotionally draining. The role of the MHP can assist nurses by offering them coping techniques, or making themselves available to talk to if they have an especially difficult case.

Nurse-patient rapport is very important for patient satisfaction, and replacing nurses leads to problems in care. It is also very expensive to replace a nurse; it has been estimated that the cost to a practice to replace one nurse in the ART clinic setting is \$250,000 (Goldstein, 2016). MHP's can ensure that nurses have adequate preparation and support for their roles, provide opportunities where personal issues can be discussed, as well as guidance on when and how to refer a patient to a MHP (Payne and Goedeke, 2007). The 2016 ESHRE survey suggests that fertility clinic staff may be willing to attend workshops to reduce the burden of their job. The workshops that were of the most interest would focus on communicating and counseling with patients, reviewing difficult cases to improve success and dealing with patient expectations. Because infertility patients have a high prevalence of anxiety and depression, appropriate training for clinical staff working with patients is important. In addition, enhancing communication skills within the organization is beneficial to reducing staff burden. Infertility treatment is an emotional journey not only for the patient but for the clinic staff. Both the patients and staff have one common goal, to achieve a viable pregnancy, and negative outcomes can burden all parties involved in the patient's treatment.

Patient Centered Care/Empathic Communication

Finally, another benefit of having MHPs in the ART clinic setting is by reducing the burden of care through focusing more on patient expectations and communication. The importance of patient centered care is dramatically undervalued by physicians. In one study, 925 patients and 227 infertility physicians completed a questionnaire which asked about the relevant importance of travel time, pregnancy rate, physician attitude, continuity of physicians, and information on treatment (van Empel et al., 2011). The last three represent patient-centered care. Patients reported more value to patient-centeredness than physicians, and even rated patient centered care more important than pregnancy rates. While the physicians considered pregnancy rates to be of the utmost importance, patients considered patient-centered care to be of more importance. In fact, the lack of patient centered care was cited as the top non-medical reason for patients to change fertility clinics.

Patients respond well to effective physician communication; a study involving 13 infertility specialists reported on the differences in patient satisfaction before and after the physicians attended a weekend retreat which focused on empathic skills (García et al., 2013). Physicians were assessed by 2146 patients prior to and following their training. There were significant improvements in patient satisfaction on perceived information quality, communication skills and time spent for first visit. The intervention was so successful in terms of patient satisfaction with care that now every employee of the center receives this training.

MHPs are qualified to teach the other members of the health care team how to communicate empathetically. Research shows that three 60-min training modules can significantly impact a physician's ability to communicate with patients and can lead to increased patient satisfaction (Riess et al., 2012). Boivin et al. (2012) suggested that an integrated approach to fertility care may benefit both patients and clinic staff. By tending to the needs of fertility clinic staff, it may indirectly benefit patient wellbeing with regard to quality of life, compliance, and decrease drop outs.

The Boston IVF Model of Mental Health Integration

At Boston IVF, we feel that we have created a model that integrates MHPs in an efficacious and cost-effective manner. All third party sessions are provided by three social workers, who offer therapy sessions as well. The three Ph.D. psychologists on staff provide individual and couples counseling with a CBT approach. These visits are usually covered by insurance. The psychologists also offer the 10-week Mind/Body Program for Infertility which helps reduce distress among patients. Any patient in crisis is guaranteed to be able to meet with or speak with one of the psychologists within 60 min of the request, including on-site visits in the PACU. All patients with an abnormal prenatal ultrasound are offered a crisis intervention session within 60 min. Also, all patients who have experienced an unsuccessful treatment cycle are offered a free 30-min session with one of the psychologists. One of the psychologists is available for crisis counseling for any employee. All employees receive one free acupuncture session, and a 25% discount for subsequent sessions. "Stress lunches" are offered on a regular basis for any employee who wishes to learn stress management techniques.

This model of care meets the needs of patients and nurses alike. The nurses know that any patient in crisis will have their concerns addressed by a MHP immediately, lessening the burden on the nurses. Patients are aware that psychological resources are always available to them, often at no cost. This model is also cost-efficient for the infertility center. It is known that the burden of care is the most common reason given by insured patients for dropping out of treatment. Efficiently treating patients' emotional distress, combined with programs designed to decrease nursing burnout, both can combine to encourage patients to remain in treatment either until their physician recommends stopping for medical/prognosis reasons, or the patient conceives a healthy baby.

Conclusions

The mental well-being of infertility patients is often overlooked and can be equally important as the physical treatments. The three roles which the MHP can provide in the ART setting include providing the means to decrease patient distress, supporting nurses to prevent burnout, and teaching health care professionals how to communicate to patients in an empathic fashion.

Patients struggling with infertility may experience severe emotional distress, even including suicidal ideation. They need knowledgeable support throughout this process, as well as effective psychological interventions specifically aimed at infertility patients. The cost of treatment termination must be considered as well. Patients who drop out of treatment are unlikely to ever conceive, and the clinic loses a source of income. The MHP can provide such interventions designed to prevent these outcomes.

Nursing burnout can have a significant impact on patients and nurses. Nursing turnover is disruptive to patients and other staff members, is incredibly expensive for the clinic, and may have long-lasting repercussions for nurses' emotional and physical health. The MHP has the training to support nurses in an effort to prevent or decrease burnout.

Empathic communication is highly correlated to patient satisfaction. The MHP can train physicians, nurses, and support staff on the most effective forms of communication, designed to decrease patient distress.

While there may be a perception that the MHP is simply an added cost, with little return on investment, in fact the potential for the MHP to decrease costs cannot be overlooked. In addition, the return on investment in terms of patient and staff quality of life cannot be underestimated. Ideally, a MHP in the ART setting will lead to less patient distress, lower dropout rates, less nursing burnout, and increased patient satisfaction.

Acknowledgment

The authors would like to thank Adam Yecies for his assistance with the preparation of this manuscript.

Acupuncture in the ART Clinic

Jeremy J Cottle and Alice D Domar, Harvard Medical School, Boston, MA, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Acupuncture is a needle-based practice most often utilized to provide pain relief, local anesthesia, and treatment for illness, although it is claimed to have a plethora of other benefits. The first description of acupuncture is from China over 2000 years ago, where at the time it was believed that illness was caused when the life force known as “qi” couldn’t properly flow through the body, or when the two forms of qi “yin” and “yang” were imbalanced. It was thought that prodding certain points with fine needles would help restore the balance and flow of qi, causing the illness to subside. Similar theories of healing were prevalent in the Western world around the same time about the balance of “humors,” and Western doctors used to think people were sick due to an excess of blood and bile within the body. While blood-letting went out of style with the advent of modern medicine, acupuncture has made a strong comeback across the world since the 1950s as a tool used primarily for pain relief. It has also been used to treat depression, fibromyalgia, rheumatoid arthritis, high and low blood pressure, many varieties of musculoskeletal pain, and infertility (Paulus et al., 2002).

So far there have been few plausible theoretical physiological mechanisms for how this one treatment can be helpful for such a wide array of ailments. Whether or not acupuncture works is controversial. Even though over 3000 trials with attempted placebo-control groups have been conducted, there is still considerable debate over the efficacy of acupuncture.

The potentially analgesic, or pain-relieving, effects of acupuncture are believed to be triggered by the needles penetrating the skin, which then releases endorphins. Endorphins are hormones that, along with other neurotransmitters and endogenous opioid-like substances, can reduce pain and have been connected with the skin penetration of acupuncture (Wang et al., 2008). Other studies have found similar physiological effects of acupuncture, like one study published in *Nature Neuroscience* that found the local release of adenosine at the site of skin deformation from acupuncture needles (Goldman et al., 2010). This release of adenosine is linked with pain relief in acupuncture studies on mice, according to a 2014 review (Gorski, 2014). Acupuncture can also be anti-inflammatory (Kavoussi and Ross, 2007). A systematic review of 34 brain imaging studies suggests that the stress and pain reduction linked with acupuncture stimulation is due to modulated brain activity in the limbic system, somatosensory cortices, and other brain areas (Huang et al., 2012).

Despite these positive connections between acupuncture and health outcomes, there remains controversy over the quality of these claims. Systematic reviews have played an important role in the promotion of acupuncture for health benefits, but one review examined 88 Chinese acupuncture-related systematic reviews for quality, finding that the impact factor of over half the publishing journals was 0, and less than half reported assessing for publication bias (Ma et al., 2012). In fact, all trials originating in Asia were in favor of acupuncture. In comparison, only 53% of review trials in the United States showed favorable outcomes from acupuncture (Vickers et al., 1998). A 2006 meta-analysis published by the Journal of Internal Medicine found the results of acupuncture treatment could not be differentiated from the placebo treatment, suggesting that medical effects could really depend on a placebo response rather than a direct physiological impact (Ernst, 2006). A 2011 analysis of 57 systematic reviews showed similar findings, suggesting that there was little evidence supporting acupuncture as an effective form of pain relief, especially considering the lack of high-quality articles on the subject, the narrow scope of health benefits in those high-quality articles, and the potential for significant adverse effects, no matter how rare (Ernst et al., 2011). In 2012, however, a meta-analysis from the Memorial Sloan-Kettering Cancer Center came out in favor of acupuncture; the conclusions were that acupuncture had a significantly greater impact on chronic pain than placebo (Vickers et al., 2012). This was promising considering the addictive properties of pain-relieving medications which also have a large number of negative side effects.

While there is continued debate on the efficacy of acupuncture, when compared to other treatments for these ailments such as pain, acupuncture poses minimal risks, and has potential for great benefits.

Acupuncture and Female Infertility

Acupuncture has been used to increase fertility since its inception in China over 2000 years ago. In modern times, the cause of infertility is usually determined through a work-up and can be corrected/treated. However, some infertility patients do not receive a diagnosis and the causes of many failed IVF cycles are unknown, in which case many patients seek out alternative treatments in an effort to increase the chances of a pregnancy. The pioneering scientific study on the impact of acupuncture on infertility was done in 2002 (Paulus et al., 2002). This randomized controlled prospective study included 160 patients undergoing assisted reproductive treatments, randomly assigning patients to either an acupuncture or control group. The acupuncture patients received 25 min of acupuncture before and after embryo transfer, while the control group rested alone for equivalent amounts of time. There was a significantly higher clinical pregnancy rate in the acupuncture group (42.5%) compared to the control group (26.3%).

This ground-breaking study, frequently referred to as the Paulus study, utilizing the “Paulus protocol,” has radically changed how many infertility patients view acupuncture. After the study was published, infertility patients flocked to acupuncture clinics and at some infertility centers, patients demanded that acupuncture be delivered on site. Some clinics reported that more than

80% of their advanced reproductive technology (ART) patients were receiving acupuncture and some acupuncture clinics were overwhelmed by the demand (Hay and Domar, 2015). However, not all subsequent research has replicated the Paulus study. The impact of acupuncture on fertility/ART success remains a topic of frequent debate.

From a physiological standpoint, one theory as to why acupuncture may improve fertility outcomes is via neurotransmitters. Specifically, acupuncture can influence fertility by modulating gonadotropin levels, specifically in the case of electroacupuncture, which can then influence ovulation through the menstrual cycle (Maliqueo et al., 2015). Acupuncture may also inhibit “uterine central nerve activity” by stimulating blood flow to the uterus, therefore increasing chances of conception. A literature review on the impact of acupuncture on IVF outcome included in its conclusions that possible mechanisms of action were neuroendocrine, increased blood flow to the pelvic region, modulating cytokines, and/or the reduction of distress (Anderson et al., 2007). Finally, considering the role that the biological stress response plays in reducing chances of pregnancy, acupuncture can improve fertility outcomes by stimulating the production of endogenous opioids that inhibit that stress response through the central nervous system (Cho et al., 1997). Some researchers dismiss these theories as simply being a placebo effect.

To account for this easy dismissal, researchers often attempt to control for the placebo effect by randomly assigning participants to either acupuncture or control groups. The most common method for creating a placebo control group is via “sham” acupuncture, in which the patient and researchers, but not the acupuncturist, are blinded to whether the patient is receiving real or sham acupuncture (Moffet, 2009). Sham acupuncture either uses non-penetrating needles (needles which touch the skin, so the patient feels a pricking sensation but the needle doesn’t penetrate the skin) or needling at non-acupuncture points, where the practice will either not specifically address the condition being studied or not be placed on the meridians typically used for acupuncture.

This sham acupuncture has played an important role in casting doubt on traditional acupuncture practices involving meridians and needling locations, as a number of studies have not produced differences between acupuncture and control groups (Moffet, 2009). Due to these findings, researchers have suggested that the therapeutic effects of acupuncture are not specifically related to acupuncture; rather, they could be due to other variables such as the relaxing environment or a placebo effect (Moffet, 2009). The aforementioned 2014 review in *Nature Reviews Cancer* found that the act of penetrating skin at meridians for the purpose of redirecting the flow of *qi* may be unrelated to the health benefits of acupuncture, as is the frequency of needling (Gorski, 2014). This aligns with the view that acupuncture is successful due to a placebo effect rather than a directly physiological effect (Gorski, 2014).

Despite the rampant issues in differentiating between real and sham acupuncture, there *are* studies showing significant positive effects of real acupuncture above and beyond the effects of sham acupuncture. A 2013 study aimed to measure the unique effects of acupuncture on fertility among women struggling to conceive, including 84 infertile patients with a history of at least two unsuccessful IVF attempts (di Villahermosa et al., 2013). Using acupuncture, control, and sham groups, this study found significant differences in clinical pregnancy rates, such that the acupuncture group exhibited significantly higher rates than both the sham and control groups, which were not significantly different from one another. This supports the unique effect of acupuncture on women’s fertility above and beyond a mere placebo effect.

Although findings such as these are encouraging for the role of acupuncture in supporting fertility in patients undergoing in vitro fertilization, the literature remains divided on the efficacy of acupuncture to improve IVF outcomes. A 2008 meta-analysis examining 13 randomized controlled trials (RCT) on acupuncture and IVF outcome found that acupuncture did not lead to a significant increase in live birth rate or clinical pregnancy at multiple points during the IVF process (El-Toukhy et al., 2008). On the contrary, a meta-analysis conducted in 2012 on 24 trials found that acupuncture with IVF patients was associated with both a higher pregnancy rate and live birth rate, but only when the type of control was considered (Zheng et al., 2012). One early review of the literature concluded that there is some evidence to support the theory that acupuncture may be associated with higher pregnancy rates from IVF as well as improved quality of life (Anderson et al., 2007). Another meta-analysis of seven trials suggested that acupuncture administered at the time of embryo transfer can be linked with improved pregnancy rates and live birth rates; however, some of this was attributed to selection bias (Manheimer et al., 2008).

Other trials produced mixed findings as well, with each taking a slightly different approach. In a 2006 RCT on 228 subjects, results showed a pregnancy rate of 31% for the acupuncture group, whereas the sham acupuncture group exhibited a 23% pregnancy rate, although the difference was nonsignificant (Smith et al., 2006). In a more recent study, acupuncture was performed at different points during the IVF process (Shen et al., 2015). This study included three randomized groups, each of which received acupuncture: one group received acupuncture 25 min before and after embryo transfer (ET), the second group received acupuncture during the follicular phase of the cycle as well as 25 min before and after ET, and the final group only received acupuncture 30 min after ET. The results showed no significant improvements in the clinical pregnancy rate for two of the groups, where acupuncture was performed only at the time of ET or 30 min after ET. However, participants who received acupuncture during the follicular phase of the menstrual cycle as well as 25 min before and after ET exhibited significantly higher pregnancy rates.

A variation of traditional acupuncture is electroacupuncture (EA), where the needles are placed in the desired location and are then attached to an electrical stimulator. An early randomized controlled prospective study using EA on 44 IVF patients showed no significant differences in pregnancy between the two groups but did show that EA was associated with significant reductions in the pulsatility index of both uterine arteries (Ho et al., 2009). A subsequent non-randomized study on EA in 21 women with diminished ovarian reserve who received 12 weeks of treatment revealed significant decreases in follicle-stimulating hormone, an indication of improved ovarian reserve (Wang et al., 2016). These improvements continued 12 weeks after the cessation of treatment. There is ongoing research on the impact of EA on pregnancy rates in infertile women.

One study described how an invitation to participate in an RCT of acupuncture as an adjuvant to IVF was received by infertile women and how they processed their decision to participate. This study found that most women who agree to RCT infertility studies described themselves as active agents searching for a better outcome for their infertility or improved outcomes for women in the future. “Their decision to participate in an RCT was motivated by factors such as opportunity, novelty and a value of science and was made after weighing various risks and benefits”. This is an important aspect of these studies because these women in most of the studies are already less fertile than the typical woman who goes through an IVF cycle (De Lacey et al., 2017). In general, women who volunteer for acupuncture studies tend to be poorer prognosis patients; women with the best quality embryos do not seem to be as anxious to volunteer for research on acupuncture.

Perhaps one of the most important points that has received minimal attention is the quality of embryos which are transferred. Presumably, there is no intervention which has the capacity of transforming an abnormal embryo into a normal one. Thus, if the women who tend to volunteer to participate in acupuncture trials have a greater chance of having poorer quality embryos to transfer, when they participate in a RCT, there is less of an opportunity for acupuncture to have a significant impact, thereby producing a ceiling effect. The only way to accurately perform an RCT is to do so only with women with good quality embryos. In the original Paulus study (2002), this is exactly what researchers did; future research should attempt to replicate these conditions. Until there is more research which only includes women with good quality embryos, the question of the impact of acupuncture on IVF is unanswered.

Acupuncture and Male Infertility

The relationship between male infertility and acupuncture has also been evaluated in a number of studies. A recent Chinese study examined whether or not acupuncture can improve male sperm quality and therefore fertility outcomes for couples. This study found that acupuncture was more effective than Western Medicine alone and as effective as traditional Chinese medicine, and its effectiveness was enhanced when combined with traditional Chinese or western medicine in improving sperm count and quality (He et al., 2015). Contrary to these findings, a meta-analysis of four RCTs examining the effectiveness and safety of acupuncture for poor semen quality in infertile males recently found that most studies were unable to find a significant difference in sperm quality associated with acupuncture (Jerng et al., 2014). However, the authors attributed the lack of significant results to poor reporting, high levels of heterogeneity, and high risk of bias.

A 2016 study found acupuncture to be an effective treatment for patients with primary infertile varicocele (an enlargement of the veins within the scrotum) and semen abnormalities, producing similar results to Western varicocelectomy treatment (Kucuk et al., 2016).

Acupuncture, Stress, and Infertility

Stress is often cited as negatively impacting the ability to achieve a pregnancy. High levels of physical stress can increase the risk of miscarriage, and chronic life stress can make it more difficult to achieve pregnancy. Infertility patients may participate in acupuncture as a way to reduce their distress, and thus increase their chance of achieving a pregnancy.

Patients who experience infertility and its subsequent treatment have high rates of depression and anxiety. High levels of distress can lower the chances of a successful embryo transfer, and may increase the risk of miscarriage. One consistent result of acupuncture in the scientific literature is that it can be a useful tool for reducing distress, which in turn may improve fertility and IVF outcomes. A 2012 study on 43 patients undergoing IVF treatment found that acupuncture significantly lowered anxiety levels when compared to the control group after four weekly acupuncture sessions (Isoyama et al., 2012). A 2010 study conducted with 57 infertile patients undergoing IVF treatment found that an acupuncture regimen was associated with lower levels of distress both before and after embryo transfer when compared to a control group without acupuncture; this difference in stress levels may have improved pregnancy rates (Balk et al., 2010). Lower perceived stress has been shown to improve pregnancy rates at the time of embryo transfer. Women with lower stress and anxiety prior to oocyte retrieval and embryo transfer tend to have higher pregnancy and live birth rates (Turner et al., 2013).

Depression, anxiety, and life stress are all detrimental to sleep and a steady sleep schedule is also essential for fertility (Summa et al., 2012). Physical stress has the potential to disrupt circadian rhythms and cyclic melatonin, which are critical to the optimal functioning of ovaries and placenta (Reiter et al., 2014). Similarly, many animal studies have been done that show that an environmental perturbation of the circadian clock can disrupt pregnancies (Summa et al., 2012). Acupuncture has been shown to help sleep disorders such as insomnia and narcolepsy. It has also been shown that acupuncture is effective in improving sleep quality and prompting relaxation in people of all ages with residual or primary insomnia (Zuppa et al., 2015). Considering the role that sleep plays in pregnancy, acupuncture's effect on sleep could have an indirect effect on pregnancy rate.

A 2011 pilot RCT examined 32 women aged 20–45 years split into acupuncture or wait-list control groups, all with a diagnosis of infertility (Smith et al., 2011). Participants in the acupuncture group received six sessions of acupuncture over 8 weeks, and then completed the Fertility Problem Inventory (FPI) to measure psychosocial factors including infertility self-efficacy, anxiety, and infertility-related stress. After 8 weeks, women in the acupuncture group reported better psychosocial outcomes than the control group, as they exhibited significantly less social and relationship concern, as well as trends toward reduced infertility-related stress, improved fertility self-efficacy, and reduced anxiety.

Conclusions

Since the publication of the Paulus study in 2002, acupuncture has been seen by many patients as a way to enhance their chance of pregnancy from ART. Although the research on the impact of acupuncture on IVF outcome is still not definitive, there is enough data to warrant its inclusion in selected patients. Women with normal-appearing embryos can be encouraged to undergo acupuncture pre- and post-embryo transfer; there are virtually no side effects and the cost of these two sessions, approximately \$150, is minimal compared to the cost of an IVF cycle.

Boston IVF is one of the largest infertility centers in the United States. An integrative care center opened on site in 2006 and was expanded in 2017. The Domar Center for Mind/Body Health now shares a waiting room with ultrasound and phlebotomy, thus giving patients the impression that it truly is an integrative approach. Included in the integrative care center are four acupuncture rooms and the Center is located next to the operating and transfer rooms. The Center employs five acupuncturists, and it is open 365 days per year, i.e., when the BIVF operating/transfer rooms are open.

When a patient is scheduled for her embryo or blastocyst transfer, she is asked whether or not she would like to schedule pre- and post-transfer acupuncture. If she expresses an interest, she is transferred to the Domar Center and she can then schedule her appointment. She is instructed to come in for acupuncture a half hour before her scheduled transfer arrival time. She receives 25 min of acupuncture prior to and following the transfer, using the Paulus protocol. Approximately one third of all transfer patients end up receiving acupuncture.

It is unknown at the current time if acupuncture leads to an increase in pregnancy rates for our patients. However, patients consistently report feeling more relaxed as they prepare for and then recover from their transfer. Perhaps more importantly, for a small investment in time and money, these patients truly feel they are doing everything within their power to increase their odds of conceiving a healthy baby.

Acknowledgments

We would like to thank Kristin Rooney, BA, and Adam Yecies for their assistance with the preparation of this manuscript.

ETHICS AND THE LEGISLATION

Global Changes in the Regulation of Reproductive Medicine

Tetsuya Ishii, Hokkaido University, Sapporo, Japan

Introduction

In 1884, an old type of infertility treatment was carried out: A Philadelphia physician inseminated a woman using sperm taken from his student (Yuko, 2016). This case of artificial insemination (AI) is believed to be the first instance of reproductive medicine involving a third-party. Nearly a century later, a UK woman, named Lesley Brown had suffered from infertility for 9 years due to complications of blocked fallopian tubes. She underwent a new reproductive technique, termed in vitro fertilization (IVF), successfully resulting in the birth of her daughter, Louise Joy Brown, in 1978 (Steptoe and Edwards, 1978). Developed countries are facing a rising average age of first birth, and advanced maternal age may affect fertility in several respects, including a compromised quality of eggs. IVF has also been used to treat such cases other than blocked fallopian tubes. Male infertility is generally associated with environmental factors, including stress, life habits, and drugs, as well as congenital factors. To assist fertility for men with few or poorly motile sperm, a reproductive technique involving the directly injection of one sperm into one egg was developed, termed intracytoplasmic sperm injection (ICSI). The first child born using ICSI was reported in 1992. Against such a backdrop, reproductive medicine, such as IVF and ICSI, has now spread across the globe.

IVF and ICSI involving a third-party have also been used to assist reproduction for medical and social reasons. Some infertile couples require a gamete donor or a surrogate mother if the partners cannot produce fertile eggs or sperm, or if a female partner has no functional uterus. Moreover, same-sex couples and men and women without a partner also make use of such third-party reproduction techniques for their family-building. However, the practice of reproductive medicine using donor gametes and/or a surrogate mother has raised ethical and social issues, particular in cross-border reproduction (Jackson et al., 2017). The sale of donor gametes (particularly eggs) has raised concerns over the exploitation and/or commodification of human reproductive cells. Some egg donors suffer health problems due to such as hormonal injection in egg retrieval. Furthermore, the use of IVF using donor gametes reduces the consistency of genetic relatedness in a legitimate birth. Disclosing to the resultant children the fact that they were conceived via donor gametes has been chief among the thorny issues raised, and some clashes have occurred between the surrogate mother and the genetic parents (ABC, 2017).

Preimplantation genetic diagnosis (PGD) involves the DNA testing of preimplantation embryos and was originally developed in order to avoid childbirths with genetic disease. Subsequently, PGD has been repurposed for social reasons in some countries, such as sex-selection to ensure that the child is a desired sex in a family or a socially preferred sex (Bayefsky, 2016).

Thus, complicated issues have occurred surrounding reproductive medicine. As to why this happened, in human society, reproduction implies family-building. Reproductive medicine can help meet the fertility and childbirth needs of homosexual couples as well as heterosexual couples. In addition, it can be used to help give birth to children of the desired number, gender, health or other characteristics. While, advances in biomedicine and the diffusion of reproductive medicine have progressed with astonishing speed. In response, some professional societies have established relevant guidelines, whereas many countries have struggled to enact relevant laws though social discussions.

The present article first describes the current state of regulation of reproductive medicine in 49 countries, then analyzes the changes from 2007 to 2016. Subsequently, it highlights important legal changes concerning specific techniques: IVF, gamete donation, surrogacy, PGD, and germline genetic modification. It also focuses on the regulation of reproductive medicine in G7 countries. Finally, future regulatory changes are discussed, with consideration of the recent advances in reproductive biomedicine.

Current State of Regulation of Reproductive Medicine

Because reproductive medicine can have a wide impact a society, its regulation should, ideally, be based on laws that are a national or regional norm with enforcement, such as the deprivation of a medical license, a fine, or imprisonment when violated. However, enacting law usually require a broad social consensus that takes at least several years. Moreover, the amendment to or the abolishment of enacted law can also take years. Social costs after the enactment, such as data registry, monitoring, inspection, and administration, are also necessary. In contrast, the establishment and amendment of guidelines on reproductive medicine is, in general less difficult, as such guidelines are typically established by professional societies or health authorities, not a national legislative assembly. Furthermore, such guidelines are intended to notify physicians of the medical standards and are largely not binding.

Fig. 1 The international regulatory landscape of reproductive medicine, as of 2016. This map was drawn according to the information in IFFS Surveillance reports 2007 and 2016. Only the regulatory state in Hong Kong was reassessed and judged “Law” in both 2007 and 2016.

The International Federation of Fertility Societies (IFFS) regularly surveys global activities regarding reproductive medicine. A total of 49 countries were selected among the countries that participated in the both IFFS Surveillance 2007 and 2016 (IFFS, 2007; IFFS, 2016). According to the IFFS Surveillance reports, such countries provided reliable data pertinent to the regulation of reproductive medicine. **Fig. 1** displays the regulatory state of reproductive medicine in these 49 countries, based on the 2016 report. The countries were categorized into three subcategories: 34 countries regulate reproductive medicine by law (69%), 12 regulate it by guidelines (24%: Brazil, Chile, China, India, Ireland, Japan, Mexico, Philippines, Singapore, Colombia, Ecuador, Jordan), and three have no relevant laws nor guidelines (6%: “None”: Malaysia, Peru, and Venezuela). Because approximately 200 countries currently exist worldwide, the data suggests that at least 17% of all countries have established laws regarding reproductive medicine. The regulatory map also shows that the 15 countries operating under “Guidelines” or no regulation (“None”) are largely located in South America and Asia (**Fig. 1**).

Changes in the Past Decade

Table 1 shows the regulatory changes in the 49 countries (**Fig. 1**), stratified by comparing the findings in IFFS Surveillance reports of 2007 and 2016. The regulatory state regarding the practice of reproductive medicine remained unchanged in the 37 countries (76%). However, the remaining 12 countries changed their relevant regulation (24%). In detail, 8 of 12 countries newly enacted laws regarding reproductive medicine. Interestingly, Finland, Portugal, Romania, and Uruguay newly enacted relevant laws, despite having no regulations at the Surveillance 2007. Of particular note, Costa Rica legally permitted IVF in 2016, despite having prohibited it for 16 years. Colombia, Ecuador, and Jordan newly established relevant guidelines.

In the past decade, the number of countries with laws pertinent to reproductive medicine has increased from 53% to 69% among the 49 countries (**Table 1**). However, Brazil, Chile, China, India, Ireland, Japan, Mexico, the Philippines, and Singapore have not changed their guidelines to laws. Malaysia, Peru, and Venezuela have continued to have no regulation of reproductive medicine.

Reproductive Medicine, Religion, and Regulation

Reproductive medicine is unique in medical disciplines. It may involve in two different individuals (typically a wife and a husband), but its direct subject is a prospective child. Additionally, reproductive medicine may also involve a third-party: a gamete donor or

Table 1 The changes in the regulation pertinent to reproductive medicine

According to the IFFS report 2007 and 2016		Countries (49)
37 countries unchanged regulation	Law (25)	Austria, Belgium, Bulgaria, Canada, Czech Republic, Denmark, France, Germany, Greece, Hungary, Israel, Italy, Hong Kong, Netherlands, Norway, Russia, Saudi Arabia, Slovak Republic, South Korea, Spain, Sweden, Switzerland, Taiwan, Turkey, United Kingdom
	Guidelines (9) "None" (3)	Brazil, Chile, China, India, Ireland, Japan, Mexico, Philippines, Singapore Malaysia, Peru, Venezuela
12 countries changed	Guidelines to law (4)	Argentina, Australia, South Africa, United States
	"None" to law (4)	Finland, Portugal, Romania, Uruguay
	Legal prohibition to legal permission (1) "None" to guidelines (3)	Costa Rica Colombia, Ecuador, Jordan

IFFS, International Federation of Fertility Societies; "None", implies having no law nor guidelines regarding reproductive medicine.

a surrogate mother. Generally, reproductive autonomy supports the practice of reproductive medicine. However, the complexity of parties concerned in third-party reproduction has made it difficult to discuss its appropriate use in society.

Religious beliefs play a large role in the manner of human reproduction or family-building in some countries. Thus, many religious groups have expressed their view toward reproductive medicine (Sallam and Sallam, 2016). Briefly, nearly all forms of Judaism, Hinduism, and Buddhism currently accept reproductive medicine. By contrast, Roman Catholicism does not accept any form of reproductive medicine, as they regard human embryos as humans and assert that a new human life must begin only through natural means and that artificial interventions at the inception of human life involve inherent dangers and are unacceptable. Most Orthodox Jews and Christians refuse third-party reproduction because they value blood lineage. Protestants, Anglicans, Coptic Christians, and Sunni Muslims accept most forms of reproductive medicine, so long as gamete or embryo donation are not involved. Likewise, Confucianism, which is associated with a preference for sons, still influences Chinese culture, and accepts all forms of reproductive medicine involving no third parties.

Thus, some religious groups largely accept reproductive medicine, while others condemn some or all types of reproductive medicine. Such religious beliefs have shaped the acceptable use of reproductive medicine in some countries, as reflected in relevant regulation.

Recent Regulatory Changes in Specific Techniques

IVF and ICSI

Based on reproductive autonomy, many countries legally permit IVF and ICSI, while some countries limit the maximum number of transferred embryos in order to prevent multiple pregnancies. For instance, relevant Spanish law stipulates that a maximum of three embryos can be transferred (Law on Assisted Human Reproduction Techniques 2006). In Turkey, only single embryo transfer (SET) is allowed for women <35 years of age in the first and second cycles of IVF, and a maximum of two embryos can be transferred to women ≥ 35 years of age or women <35 on the third or further cycles (Legislation concerning assisted reproductive treatment practices and centers 2010). Likewise, the Japan Society of Obstetrics and Gynecology (JSOG) adopts the SET policy (Takeshima et al., 2016).

Notably, Costa Rica became the only country explicitly prohibiting IVF in 2000 because its Constitutional Court ruled that IVF creates excess embryos and violates their right to life, strictly according to Roman Catholicism (Lemaitre and Sieder, 2017). In 2012, the Inter-American Court of Human Rights ruled that the IVF prohibition violates the right to privacy, liberty, personal integrity, and to form a family. On February 26, 2016, Costa Rica lifted its 16 years IVF ban after President Luis Guillermo Solís signed Executive Decree No. 39210-MP-S in 2015.

Reproduction With Gamete Donation

As mentioned in the Introduction, AI with donor sperm has been practiced for infertile people for over a century. With the advent of IVF, the reproductive use of donor eggs as well as sperm has been increasing for those suffering from infertility due to advanced reproductive age (particularly in women), cancer treatments, and unknown causes. Moreover, reproductive medicine involving gamete donation has recently been practiced for lesbian couples and single mothers, and it can also be used to aid gay couples and single fathers if surrogacy is available.

In the USA, gamete donation is liberally performed to satisfy such medical and social needs, and is generally allowed at the federal level, although the state of Louisiana prohibits the sale of human oocytes (La Rev. Stat 9:122). However, countries that permit reproduction using donor gametes are likely to face social issues due to inconsistencies between legitimate parenthood and genetic parenthood. For this reason, reproductive medicine involving gamete donation is typically regulated from three standpoints of intended parents, gamete donors, and resultant children. For intended parents, the parental authority in

reproduction using donor gametes is stipulated by such as civil law. Even in cases wherein gametes donated by a third-party are used, the woman who gives rise to the child is deemed a legitimate mother if statutory requirements are satisfied. Likewise, a legitimate husband is deemed a legitimate father if he acknowledges the child as his own. Gamete donors have no obligation to foster the resultant children, if they satisfy legal requirements, such as the abandonment of parental authority. In some countries, including the Czech Republic (Act on Specific Health Services 2011), Israel (Egg Donation Law 2010), and Spain (Law on Assisted Human Reproduction Techniques 2006), gamete donors must be anonymous. Moreover, the maximum number of gamete donations is frequently regulated to avoid consanguineous marriage between people born from an identical donor, and to protect them from health problems after egg retrieval, such as ovarian hyperstimulation syndrome. Some countries, such as Canada (Assisted Human Reproduction Act 2004), Czech Republic (the law shown above), India (National Guidelines for Accreditation, Supervision & Regulation of ART Clinics 2005), Taiwan (Artificial Reproduction Act 2007), and Israel (the law above), permit the reimbursement of necessary costs such as travel expenses and/or wage loss, even if gamete donation is understood to be an altruistic behavior. Other countries, such as China (The Human Assisted Reproductive Technology Specifications and the Human Assisted Reproductive Technology and Human Sperm Bank Ethical Principles 2003), prohibit any commercialization of donor gametes. For people born using donor gametes, some countries, such as Victoria state in Australia (Assisted Reproductive Treatment Amendment Act 2016), Sweden (Genetic Integrity Act 2006), Switzerland (Act on Medically Assisted Reproduction 1998), the Netherlands (Artificial Insemination: Donor Information Act 2002) and the UK (Human Fertilization and Embryology Act 1990), legally guarantee the right to access donor information, while such as the Czech Republic, Israel, and Spain do not grant any such rights as they prioritize donors' anonymity, as mentioned above.

Conversely, some countries have remained against reproductive medicine involving gamete donation. In Japan, the JSOG permits its members to perform AI using donor sperm, but forbids other third-party reproduction under their guidelines. Italy, where Roman Catholicism is the dominant religion, initially prohibited reproductive medicine gamete donation (Law on Rules in the Field of Medically Assisted Reproduction 2004). However, in 2014, the Constitutional Court lifted the ban on gamete donation by judgment 162/2014. Of particular note, Turkey, in which Sunni Muslims are dominant, prohibited all medical assistance in conception using donor gametes (Legislation Concerning Assisted Reproductive Treatment Practices and Centers 2010). The Turkish law also prohibits citizens from going abroad to seek donor gametes for reproduction. Probably, Turkey has the most strictest prohibitions against reproduction using donor gametes (Gürtin, 2016).

Surrogacy

Surrogacy is a form of third-party reproduction in which a woman consents to carry a pregnancy for intended parent(s) who cannot conceive for medical reasons or those who are a gay couple. There are two forms of surrogacy: traditional surrogacy and gestational surrogacy. Traditional surrogacy uses the surrogate mother's egg for conception. In contrast, gestational surrogacy is performed by transferring embryos made through IVF with eggs from the intended mother or a donor. Thus, the advent of IVF has assisted gestational surrogacy. However, pregnancy and gestation involve psychological burden and health risks for the surrogate mother. Moreover, the legal procedures for parenthood following surrogacy are complicated due to the typical legal assumption that a woman giving birth to a child is the legitimate mother of the child. Therefore, a surrogate mother is required to formally abandon parental authority, and the intended parent(s) then adopt the child born.

However, some clashes have occurred after childbirth in cases where a surrogate mother refuses to deliver the child to intended parents or where the intended parents refuse to accept the child (ABC, 2017). Surrogacy is likely to become more problematic, particularly in case involving payment to a surrogate mother. Commercial surrogacy has raised concerns, such as the exploitation and commodification of woman's bodies for client's family building. While, surrogacy can be altruistically performed in some countries, with the surrogate mother receiving no compensation other than reimbursement of medical and other expenses (Jackson et al., 2017). Altruistic surrogacy is sometimes considered among the relatives of an intended mother; as such, foreigners can experience difficulties in finding suitable surrogates.

Countries have responded differently to the legality of and payment for surrogacy in their policies. Some countries permit only altruistic surrogacy under relevant law, including Canada (the AHR Act 2004), Greece (such as Law on Enforcement of Medically Assisted Reproduction 2005), Israel (Surrogacy Law 1996), the Netherlands (guided by the Criminal Code), South Africa (Children's Act 2005), the UK (Surrogacy Arrangements Act 1985), and several states in Australia (except the Northern Territory). However, commercial surrogacy has been offered in several countries with lax regulations, including Georgia (Law on Health Protection 1997), Russia (Federal Law on the Fundamentals on Protection of Citizens' Health 2011), Ukraine (The Family code of Ukraine), and a few US states (Arkansas, California, Illinois, and Maryland). Other countries largely prohibit both types of surrogacy by law or under guidelines for medical, ethical, social, and religious reasons.

In Asia, important changes were recently made or attempted regarding the regulation of commercial surrogacy (Jackson et al., 2017). Thailand, which acknowledged itself as the "Health tourism hub of Asia," has gathered substantial attention from foreign (infertile) patients seeking surrogacy that is inaccessible in their home countries. However, international troubles recently occurred surrounding commercial surrogacy. As a result, Thailand legally banned commercial surrogacy for foreign tourists, by enacting the Protection of Children Born from Assisted Reproductive Technology Act 2015. In India, commercial surrogacy has been practiced since 2002. Although lax regulations had attracted foreigners seeking commercial surrogacy, clashes occurred between surrogate mothers and the intended parents. Thus, the Cabinet approved Surrogacy (Regulation) Bill 2016 to regulate commercial surrogacy.

Preimplantation Genetic Diagnosis (PGD)

The world's first PGD reported in 1990 from the UK intended to avoid the birth of children with X-linked genetic diseases by selecting female embryos through a genetic analysis of biopsied embryonic cells. Subsequently, PGD to select human embryos without a pathogenic mutation has spread worldwide. However, the role of PGD also increased at fertility clinics, raising ethical controversies. Although PGD has also been used to screen euploid embryos to increase the implantation rate and/or avoid miscarriage, the efficacy of the preimplantation genetic screening (PGS) is controversial and requires further clinical studies. Notably, the use of PGD for social sex-selection has raised concerns, such as the potential for the reinforcement of sex discrimination, particularly against women (WHO, 2017).

The USA has no federal regulations regarding the use of PGD at clinics (Bayefsky, 2016). Indeed, PGD are liberally practiced in the USA, including the embryo selection to avoid the birth of a child with genetic diseases, the screening of aneuploid embryos (PGS), social sex-selection, and "the selection of a disability". In Western Europe, many countries sanction PGD to avoid the birth of children with genetic disease but prohibit it in cases of, for example, social sex-selection under relevant law (Bayefsky, 2016).

Some countries prohibited the DNA testing of the human embryos for a long time. Germany prohibited PGD under the Embryo Protection Law 1990, but legally permitted it by enacting the Law regulating preimplantation genetic diagnosis 2011. At that time, Austria, Italy, and Switzerland, which are located close to each other, were the only remaining countries that prohibited PGD in Western Europe. Their predominant religion (Roman Catholicism) might have influenced their PGD-prohibitive policy. In 2015, Austria amended the Law on Reproductive Medicine 1992. Although the provision on the prohibition of PGD remained, the amendment granted the exceptional use of PGD in cases of serious conditions. In Italy, which had prohibited PGD with the enactment of Law 2004, the Constitutional Court ruled that couples who are carriers of genetic diseases have the right to undergo PGD in 2015. Additionally, Switzerland, which prohibited PGD under Reproductive Medicine Act 1998, recently held a referendum to lift the ban on PGD in 2016 after both the Federal Council and Parliament recommended it. Therefore, PGD for avoiding the birth of children with genetic disease is becoming widely accessible in Western Europe.

Recently, Asia also saw legal changes regarding the practice of PGD. In Thailand, PGD for social sex-selection had been offered to prospective parents including foreigners. However, Thailand legally banned social sex-selection by enacting the Protection of Children Born from Assisted Reproductive Technology Act 2015.

Germline Genetic Modification

Reproduction involving germline genetic modification has been regarded as taboo for clinical and ethical reasons, such as the serious risk to future generations, the transgression of the natural and divine laws, and the potential misuse for human enhancement for social purposes. Indeed, a legal survey performed in 2015 suggested that 74% of 39 countries prohibit human germline genetic modification by laws or guidelines (Ishii, 2017). In 2015, the UK became the first country that legalized a form of germline genetic modification under Canada. The permitted mitochondrial donation is germline mitochondrial DNA manipulation involving nuclear transfer to an enucleated donor egg or zygote made using a donor egg to reduce the load of pathogenic mitochondrial DNA, and prevent the onset of mitochondrial diseases in the offspring. Immediately after the legalization in the UK, a group led by a US physician first performed egg nuclear transfer to prenatally prevent the onset of mitochondrial disease in the USA and shipped the resulting embryo for transfer to their clinic in Mexico. Although it resulted in the birth of a boy, the legality of such a cross-border use of germline genetic modification is currently controversial (Palacios-Gonzalez and Medina-Arellano, 2017).

In 2015, a Chinese group reported basic research in which the correction of a pathogenic mutation in human embryos was attempted using a robust genetic engineering tool, known as genome editing. However, this attempt raised profound concern worldwide (Ishii, 2017). That same year, the USA established the Consolidated Appropriations Act 2016 Sec. 749, which prohibits the Food and Drug Administration from using the federal budget to review or approve applications for exemptions to the investigational use of biologics in which a human embryo is intentionally created or modified to include a heritable genetic modification. In 2016, Israel approved Amendment Law No. 3 Prohibition on Genetic Intervention (Human Cloning and Genetic Change in Reproductive Cells), 5776/2016 (valid till May 23, 2020). Despite the advent of genome editing techniques, such as CRISPR/Cas9, most countries will probably maintain their legal prohibition of human germline genetic modification.

Regulatory Situations in the G7 Countries

The regulation of reproductive medicine as of 2017 was compared in G7 countries, considering on their clinical activity and outcome according to the latest International Committee for Monitoring Assisted Reproductive Technologies (ICMART) world report 2010 (Dyer et al., 2016) (Table 2). These countries have made only three major changes in their regulation of reproductive medicine since 2010; Italy's legalization of gamete donation in 2014, the UK's legalization of mitochondrial donation in 2015 and the USA's legal ban of the FDA's use of the federal budget to review the clinical use of germline genetic modification in 2015.

Table 2 Regulatory state on reproductive medicine (RM) in G7 countries, as of October 2017

Country	Number of clinics ^a	Treatment cycles ^a	Babies/asp. cumul. (%) ^a	Reproduction using gamete donation (GD) is:	Surrogacy (S) is:	Preimplantation genetic diagnosis (PGD) is:	Germline genetic modification (GGM) is clinically:
Japan	591	242,833	19.9	Prohibited	Prohibited	Permitted (medical use only)	Prohibited
USA	474	176,214	59.2	Allowed	Permitted in some states even if commercial	Allowed (medical and social uses)	Prohibited (FDA's review banned)
Italy	202	56,419	20.7	Permitted	Prohibited	Permitted (medical use only)	Prohibited
Germany	124	75,701	32.6	Permitted (sperm donation)	Prohibited	Permitted (medical use only)	Prohibited
France	107	85,122	29	Permitted	Prohibited	Permitted (medical use only)	Prohibited
UK	72	57,482	39	Permitted	Permitted (altruistic only)	Permitted (medical use only)	Prohibited (except mitochondrial donation)
Canada	28	17,926	45.9	Permitted	Permitted (altruistic only)	Permitted (medical use only)	Prohibited

In Japan, RM is largely regulated by Japan Society of Obstetrics and Gynecology *guidelines* (GD, S, PGD) and Ministry of Health *guidelines* (GGM).

In the USA, RM is generally allowed at the federal level. The Fertility Clinic Success Rate and Certification Act 1992 requires clinics to annually provide data for all procedures to the Centers for Disease Control and Prevention. Some state laws guide the practice of GD and S. GGM is indirectly prohibited by the Consolidated Appropriations Act 2016.

Italy regulates RM by Law on Rules in the Field of Medically Assisted Reproduction 2004. However, in 2014, the Constitutional Court lifted the ban on GD.

Germany regulates RM primarily by the Embryo Protection Act 1990. PGD has been legal since Law 1990 was amended by the Law regulating preimplantation genetic diagnosis 2011.

France regulates RM by Law on Bioethics of 2011, Bioethics Law 2004, and Law 1994 on the Donation and Use of Elements and Products of the Human Body, Medically Assisted Procreation, and Prenatal Diagnosis.

The UK regulates RM by the Human Fertilization and Embryology Act 2008 and 1990 and the Surrogacy Arrangements Act 1985. Mitochondrial donation is permitted by the Human Fertilization and Embryology (Mitochondrial Donation) Regulations 2015.

Canada regulates RM primarily by the Assisted Human Reproduction Act 2004.

^aData in 2010 from Dyer, S., et al. (2016). *Human Reproduction* 31(7), 1588–1609.

These seven developed countries differ markedly in the number of fertility clinics and treatment cycles (Table 2). According to the ICMART world report 2010, Japan and the USA were the most active countries among the 60 countries examined, having hundreds of clinics and more than 100,000 treatment cycles per year. Of particular note, the total number of treatment cycles for 2010 in Japan was 242,833, which is approximately 14.8% of the total cycles 2010 across 60 countries. In Japan, the JSOG guidelines adopt a SET policy and prohibit reproductive medicine involving gamete donation, based on the request of the Ministry of Health. This is the direct opposite to the regulatory state in the USA, where gamete donation is largely allowed, and some states also permit commercial surrogacy. However, Japan showed a lower rate of childbirths per egg aspiration in 2010 (19.9%), than the USA (59.2%). The situation in Japan suggests the possibility that many patients repeatedly undergo IVF or ICSI using their own gametes. This rate is similar to that of Italy (20.7%), which is the third-most active country but had legally banned gamete donation until 2014, as discussed above. The rate of childbirths per egg aspiration ranges from 29% to 45.9% in the four western countries. Of note, Germany prohibits egg donation by the Embryo Protection Law. The gamete donation-prohibitive policies of Japan and Italy may partially account for the relatively low rate of childbirth following assisted reproduction.

With regard to regulations of surrogacy, the USA is unique among the seven developed countries, as some US states permit commercial surrogacy (Table 2). The other six countries wholly prohibit surrogacy or permit only altruistic surrogacy. Likewise, the USA allows the medical and social uses of PGD, whereas the other countries permit its use for only for medical purposes such as the avoidance of genetic disease in offspring (Table 2). In Japan, the JSOG guidelines permit PGD to avoid the birth of children with genetic conditions, but ban the practice of PGS for ethical reasons. Concerning the clinical use of human germline genetic modification, the UK is the first country that legalized mitochondrial donation. However, the other six countries largely ban it by law or guidelines (Table 2).

Future Regulatory Changes

As reproductive medicine has spread worldwide, its regulatory landscape has globally changed, reflecting ethical, religious, and social aspects. The number of countries with laws of reproductive medicine has gradually increased in the past decade, although some have not changed their relevant guidelines or continue to have no regulation of reproductive medicine.

In the early days of reproductive medicine, regulatory issues frequently occurred in reproductive medicine involving third parties. With advances in biomedicine, new issues will likely emerge in reproductive medicine involving no third parties, such as next-generation sequencing-PGS and germline genetic modification by genome editing. Such reproductive medicine can be justified by advocating parental autonomy as well as its safety in some countries. However, with the spread of cross-border reproduction, many countries will have to establish clear regulations on upcoming reproductive techniques, conducting deep discussions of its ethical, social, and religious implications. In so doing, the welfare of future children and parental autonomy will be weighted to shape appropriate regulation in each country and, hopefully, in a global society.

Cross-Border Reproductive Care

Guido Pennings, Bioethics Institute Ghent, Ghent, Belgium

© 2018 Elsevier Inc. All rights reserved.

Introduction

Cross-border reproductive care (CBRC) (more commonly called “reproductive tourism”) refers to the phenomenon of people traveling from one country where treatment is unavailable for them to a country where it is available. There is a general lack of empirical data on the prevalence of CBRC. Most published data are based on gross estimates and the studies are often methodologically lacking. In the only European study to date, the size of the phenomenon was estimated around 24,000–30,000 cycles per year minimally (Shenfield et al., 2010). Detailed numbers on incoming patients only exist for Belgium (Pennings et al., 2009). Attempts have been made to get some insight into what is happening in the United States and Canada but these were not very successful for lack of cooperation by clinics.

The accumulation of small qualitative studies on patients shows that there are many different types of patients who make different trajectories for different reasons and under diverse conditions. The term CBRC covers a large set of heterogeneous activities. As a consequence, it is difficult to make broad statements on its characteristics. It is clear, however, that some preliminary conditions have to be present before the phenomenon can develop. The most important one is the availability of information. The internet allows people to look for alternatives and to find out where the solution can be obtained and under which conditions. Other helping factors are cheap flights, willingness of clinics to adapt protocols (e.g. part of the treatment can be done at home), and special arrangements for foreign patients (interpreters, insurance ...).

Reasons for Crossing Borders

The reasons why people seek infertility treatment abroad can be put in three categories: treatment cost, treatment quality and treatment availability. First, as for other types of medical tourism, the treatment cost is an important motivator. Most countries reimburse only a limited number of cycles (1–3) and as a consequence most patients have to pay out-of-pocket. A second possible motivator is treatment quality. This element may refer to numerous aspects of the treatment: success rate, length of the waiting lists, general attitude of the doctors, patient-friendliness of the treatment and privacy considerations. A third factor is the availability of treatment. Again several aspects can be discerned: treatment might not be available because of lack of expertise or equipment (preimplantation genetic diagnosis), certain groups of patients are excluded from treatment on the basis of certain characteristics (age, sexual orientation, marital status...) and certain interventions are forbidden by law because they are considered ethically unacceptable (such as oocyte donation and social sexing) (Pennings, 2004).

Often, several of these factors are intertwined. For instance, legislation that denies certain groups access to donor sperm (like lesbian couples in France) will also affect the waiting time for donor sperm in the country. In a study on the patients going to Belgium for infertility treatment, several instances of a direct correlation between regulation in the country of residence of the patient and the extent of the patient flow towards another country were found (Pennings et al., 2009). When the Netherlands abolished donor anonymity by law in 2004, the number of Dutch patients attending Belgian fertility clinics for donor sperm doubled because of the long waiting lists at home and patients who wanted anonymous sperm.

Law Evasion

Legal diversity is a necessary condition for CBRC. Within Europe, there are not two countries with similar rules on all aspects of medically assisted reproduction. The single most important driver of CBRC is law evasion (Shenfield et al., 2010). The attitudes towards CBRC are largely determined by people's attitude towards this reason. There are three possible manners in which states can respond to CBRC: coerced conformity, international harmonization and moral pluralism (Pennings, 2004).

Coerced conformity: Some people want the government to take steps to stop citizens from going abroad. However, such defensive laws would be impossible to reinforce as one cannot know with certainty that people go abroad for medically assisted reproduction and one cannot know when citizens return that they had treatment abroad (apart from foreign surrogacy of course because they have to bring in the child). Moreover, legislation on medically assisted reproduction is (mostly) limited by the territoriality principle, that is, the laws only apply to actions performed on the national territory unless explicitly stated otherwise.

International harmonization: Another possible reaction to legal diversity is legal harmonization. Especially within the European context, people believe that a European law on medically assisted reproduction would strongly reduce the number of movements. It is, however, highly unlikely that a European consensus could be reached. Legislation on assisted reproduction touches very personal and emotional domains such as family building, marriage, and child welfare. National legislation on such issues is molded by each country's cultural, political and historical background and without a European common cultural basis, a European law would lack a firm foundation.

Moral pluralism: The last regulatory position is that states enact moral pluralism regarding citizens who seek locally prohibited treatments in other jurisdictions. That means that, although the state prohibits certain services, it recognizes the right of citizens with a different opinion to pursue such treatments elsewhere. This position displays a pragmatic and tolerant attitude.

Gamete Shortage

Beside law evasion, gamete shortage is the most important driver of CBRC. The shortage generally has several causes among which the general attitude towards genetic relationships and the perception of gamete donation as an intrusion into the family. Moreover, most European countries spend very little money and effort on campaigns to promote gamete donation. The most likely explanation for this reticent position is the controversial nature of gamete donation (socially, psychologically and morally) reinforced by secrecy and embarrassment. It is not surprising that most countries struggle with a shortage. Self-sufficiency, an ideal put forward for organ and blood donation, would decimate the number of cross-border movements.

The situation is different for sperm and eggs. Many European countries obtain sperm from Danish sperm banks. It is well known that the Danish banks ship thousands of samples around the world every year. There is no precise empirical data but press briefings by these banks give a certain idea about the extent of the trade. In Belgium, for instance, about 60% of all sperm comes from Denmark. This fact is generally ignored also because of the invisibility of these movements, in contrast to patients moving. Countries that do not import sperm generally have waiting lists going from 1 to 2 years.

For eggs, the situation is generally worse and the waiting lists are longer. Given the effort required for women to donate, relatively few women volunteer for the task. In this case, most candidate recipients head for Spain. Half (52%, $n = 15,600$) of all egg donor cycles in Europe are performed in Spain (Kupka et al., 2016). Again, however, there is scarcity of reliable empirical data on cross-border movements. According to Hernandez and de la Fuente (2010), the number of non-resident cycles in Spain can be calculated around 5000–10,000 with a large incidence of egg donation.

According to many people, the success of the Spanish centers can be explained by the fact that they pay the donors. However, this can surely not be the only explanation. Spanish centers give 900€, not as payment but as compensation for loss of time, inconvenience, pain etc. Obviously 900€ is a lot of money and may work as an incentive for women to donate. However, a look at the “compensation” schemes of other countries shows that many other countries are paying approximately the same amount or more. In Belgium, Greece, Poland, Russia, United Kingdom, and Ukraine, sums comparable to the 900€ are provided to egg donors (Pennings et al., 2014).

The question of payment has been debated for decades. It is part of the larger evolution towards commercialization in medicine. Increasingly, market rules are infiltrating all aspects of health care. However, resistance against payment for body material is still strong in Europe. In the United States, no shortage of gametes exist but then payment is considered normal. Depending on the characteristics of the donor, the going rate is between 5000 and 10,000\$. In Europe, several statements by the European parliament have emphasized the gratuity rule. Also in the Tissues and Cells Directive of 2004, non-commercialization is put forward as a central principle. However, this Directive also states that ‘donors may receive compensation, which is strictly limited to making good the expenses and inconveniences related to the donation’. The main point of discussion is the part on inconveniences. If only proven expenses can be covered, one can label this reimbursement. In case of compensation for non-financial losses, one speaks of payment. The question then becomes when compensation turns into reward and remuneration (Nuffield Council on Bioethics, 2011). To avoid payment, only reimbursement of proven expenses would be acceptable. However, it is not clear why non-financial losses (time, inconveniences, pain, etc.) cannot be compensated. Still, when non-financial losses are compensated with money, the distinction with payment and wages becomes small, if not untenable. A possible solution might be to offer non-financial compensation such as free vacation, a voucher for a weekend trip or something similar.

Since many patients leave their country looking for gametes abroad, one part of the solution would be to recruit more donors at home. More of an effort should be made by all countries to become self-sufficient as far as donor gametes is concerned. Every donor recruited at home is a patient less who has to travel to another country to obtain gametes.

Main Risks and Challenges in CBRC

CBRC has a bad reputation and is usually presented as a problem. Many organizations warn their members about traveling to another country. An analysis of the statements of four major organizations (European Society of Human Reproduction and Embryology (ESHRE); Human Fertilization and Embryology Authority (HFEA); International Federation of Gynecology and Obstetrics (FIGO); and Infertility Consumer Support for Infertility (iCSI)) on the types of risks and challenges related to CBRC results in the following list of major risks: violation of or non-compliance with safety standards (multiple pregnancy, donor screening, ovarian hyperstimulation syndrome); violation of or non-compliance with quality standards (success rates); confidentiality of patient information (medical records); lack of or insufficient psychosocial and medical counseling (language and culture); financial implications (real cost, reimbursement...); differences in gamete donation arrangements and surrogacy (anonymity, legal rights and obligations); and legal recourse after treatment (malpractice, indemnification, insurance ...).

Several strategies have been developed to deal with these issues. The European Union has enacted laws and directives to guarantee safety of care and to protect patient rights. ESHRE published a good practice guide for cross-border reproductive care specifically directed at clinics and practitioners (Shenfield et al., 2011). Health insurers worldwide are offering portable insurance packages that provide financial and legal support for cross-border patients.

To avoid tendentious presentations, the assumed dangers of cross-border reproductive care should be corroborated by empirical evidence. At the moment, a lot of anecdotal evidence circulates on the internet as well as in academic literature but, given the possible conflict of interest of the sources of the stories, this evidence should be handled with care.

The literature shows that CBRC would hold a risk for three important values, that is, safety, autonomy, and justice.

Safety

Multiple pregnancy leads to a strong increase in obstetric complications, perinatal morbidity, maternal and child mortality rate, congenital malformations, pre-term birth, and long-term social, psychological and financial difficulties. The occurrence of this side effect of ART is a test case for the moral quality of the field. The most recent report of pregnancy rates in Europe after medically assisted reproduction indicates that there are still huge differences: in 2011, twin pregnancies after IVF or ICSI occurred in 4.9% of cases in Sweden, 22.1% of cases in Spain, and 41.5% of cases in Greece ([Kupka et al., 2016](#)). Whereas CBRC is often cited as leading to more multiple pregnancies, one might also argue that patients from countries with a high multiple pregnancy rate should, for their own and their child's safety, seek treatment in countries with a low multiple pregnancy rate. The conclusion is that whether or not CBRC jeopardizes patients' health depends on the starting conditions at home and on the general conditions in the destination country.

It seems that generally speaking most clinics in member states of the European Union follow good practice guidelines, partially imposed by the European Tissues and Cells Directive, and that risks for the patients are not significantly higher when they seek treatment elsewhere. For countries outside the European Union, things are less clear but still there are no studies showing that there are major reasons for concern as far as safety is concerned.

Autonomy

Autonomy refers to the right of the patient to make important decisions in his or her life in accordance with his or her life plans and values. Medical interventions generally qualify as important decisions and thus require permission from the patient. In the context of medical treatment, autonomy is generally operationalized in the informed consent. Two important aspects are involved here: the provision of information and counseling. A person can only make an informed decision when he received all the relevant information. More specifically, this implies information on success rates, complications, costs etc. This is a difficult job since these parameters frequently depend on the personal characteristics of the patient (age, body mass index, etc.) and may not be clearly known before the treatment. Nevertheless, there are reasons for concern. Most patients choose the clinic abroad through the internet. There are very few studies on the quality and reliability of information on websites of infertility clinics. However, as for all other types of commercial activities, websites are used to attract customers and there is no reason to assume that this would be different in assisted reproduction. Points that raise concerns are exaggerated success rates (mainly by taking a mean that completely ignores the increased age of foreign patients), downplaying of potential risks (especially when multiple pregnancies are concerned), and subtle commercial messages to convince patients. Several studies have indicated that a large percentage of patients use the internet as their prime source of information, although there are large international differences ([Shenfield et al., 2010](#)). However, despite these concerns, no empirical studies have demonstrated a real danger. Moreover, even if shortcomings would be demonstrated, this would still not count as an argument against cross-border care as such. Information could be provided by other, more reliable sources such as local physicians, patient organizations, etc. Another solution could be to have quality labels accorded through independent international organizations to clinics.

The second issue regards counseling especially for socially and psychologically more complex interventions such as gamete donation. It is important that patients receive counseling regarding the possible aspects, consequences, and psychological repercussions of such treatments. A possible problem here might be the language. Receiving counseling in a foreign language is certainly not ideal. Talking about personal, intimate, and difficult issues such as feelings, self-esteem and sexuality is hard in any language but even more so in a foreign tongue. One may appeal to interpreters but many psychologists are reluctant to do so. In addition, there may be a cultural gap: some things may not be discussable in certain cultures or between certain persons, others things may be seen as self-evident by the counselor but not by the patients. Two points should be made here: first, many larger clinics with significant numbers of foreign patients have hired doctors from several nationalities, precisely to accommodate these patients. They are welcomed, counseled and treated in their mother tongue. Second, if there are concerns about counseling for certain types of interventions, this should be an overall concern that applies to other treatments as well and also to patients of foreign origin resident in the country. So, although appropriate counseling is certainly relevant for the assessment of cross-border treatments, it should be evaluated in a broader perspective.

A final remark regarding autonomy: cross-border traveling allows patients who do not have access to a certain type of treatment at home to fulfill their child wish abroad. This brings an enormous increase in their autonomy. This advantage may easily outweigh the possible negative effects of treatment abroad.

Justice

Many countries reimburse only a limited number of IVF cycles (or none at all), and if these are unsuccessful or if patients want more children, additional cycles may become a serious financial burden. This burden might be considerably lighter if the patients seek

treatment abroad. The direct cost of an ART cycle is estimated around 10,000€ in the United States, 4500€ in the United Kingdom and 2500€ in Belgium (Connolly et al., 2010). There are two dimensions to justice: access and equality. Access means that people should not be discriminated, that is, should not be excluded on the basis of ethically irrelevant elements. One such element is wealth, at least in countries where infertility treatment is considered to be part of the basic health care package. Equality refers to the fact that all people should be treated equally.

The level of subsidization or public funding determines financial access and thus indirectly the overall access to infertility treatment. If infertility treatment is part of basic health care and a country does not provide a reasonable number of IVF cycles, only the rich will be able to access treatment. When people have to pay out-of-pocket at home, they may be able to pay a treatment abroad which they could never afford at home. If this is the case, justice as access to treatment may be improved for poor people by crossing the border.

The situation is completely different for patients who travel because they want to evade a restrictive legislation or because they want to avoid a long waiting list. There indeed those who have the financial means can travel while the others cannot. Those who use the argument of justice to reject the possibility of going abroad focus on the equality aspect. Equality can be established by making sure that either no one has access to treatment or that everyone has. So the restrictive way would be to try to prevent people from going abroad. That would install equality since no one (not even the rich) would have access. However, another way in which this inequality could be avoided would be to introduce portability of health insurance for all. That means that people who go abroad to obtain treatment that is not available at home would still be reimbursed by their health insurance. Most countries will try to avoid this scenario since they will see this as a form of complicity with wrongdoing. In fact, when the European Directive on patient mobility was discussed, countries explicitly demanded the guarantee that they would not be obliged to reimburse treatments that were not available in their territory. From the start, the member states wanted to keep a certain degree of control, both on health care expenditures and on the type of treatment they would be obliged to pay for abroad. It was specified that they would not have to reimburse ethically controversial medical services like euthanasia, DNA testing or IVF when these services are not allowed or not reimbursed at home (European Parliament and Council, 2009). Of course, another solution would be to adopt a more lenient legislation that does not exclude large groups in the population and does not force them to seek help in another country. In other words, rather than blaming the victim from finding a way out, one may reconsider the causes of the movements.

Conclusion

Cross-border reproductive care is a multifaceted phenomenon. The empirical evidence has demonstrated that it is difficult to compose a profile of the “reproductive tourist.” Moreover, the whole field is developing fast. International chains of clinics emerge, the introduction of European legislation specifically on patient mobility and portability of health insurance may lead to an increase in movements, and changes in national legislation could alter patient streams quite drastically. Since it is unlikely that the main causes of cross-border reproductive care will drop away any time soon, the first and minimal step now is to try to reduce harm to patients (and donors) as much as possible. This can be done by better regulation of clinics, improved control of safety standards, and objective information provided to patients. However, cross-border care is not necessarily a bad thing. Many risks and complications currently attributed to cross-border reproductive care are not really related to crossing borders. Still, since patients should have access to treatment at home, and since cross-border treatment frequently adds an extra burden to the already quite difficult project of infertility treatment, governments should at least look at the possibilities of eliminating the reasons why the citizens leave.

Modern Ethical Dilemmas in ART

Introduction

Medically assisted reproduction offers people an increasingly broad spectrum of techniques to have the child they long for. These techniques can be subdivided in two categories: those using the intended parents own genetic material/gametes and those using donor genetic material/gametes. For the large majority of the people, the applications in the latter category are “solutions of the last resort”: only if there is no way that a couple or person can have a genetically related child will a non-genetically related child be considered. However, almost all the techniques to bypass a defect of the reproductive system imply manipulations and modifications of which the consequences for the long term health of the future offspring are unknown. One recent example that caused quite some concern is mitochondrial transfer. Women at risk of transmitting a mitochondrial disorder to their offspring either transfer healthy mitochondria from a donor into their oocytes or transfer the nucleus of their egg into an enucleated donor oocyte. The health consequences of this manipulation are unknown. The important point is, however, that this issue could be avoided by using donor eggs. Still, despite the risks, one goes ahead with the development of the technique. The same applies to people with known increased risks of transmitting a genetic disease who go through multiple cycles of IVF and PGD while donor gametes would solve the issue. At the same time, the use of donor gametes is not self-evident or easy either. In the present climate in which much emphasis is put on the person of the donor, the importance of knowing one’s genetic origin in order to develop one’s identity and the strong value attached to the genetic relationship between the donor and the child, gamete donation is increasingly confronted with moral and psychological problems. Moreover, there is a shortage of donor gametes (in particular of eggs) in many countries, resulting in long waiting lists.

In this article we will look more closely at two applications that illustrate this general problem: oocyte cryopreservation for healthy women and stem cell derived gametes. Both examples show in different ways the importance of genetic parenthood.

Oocyte Cryopreservation for Healthy Women

One of the interventions in ART that has been the topic of ethical debate for several years now is oocyte cryopreservation in anticipation of age-related fertility decline, known as “social egg freezing”, “elective egg freezing”, “non-medical egg freezing” or “AGE banking” (whereby AGE is an acronym for Anticipated Gamete Exhaustion). Although the first healthy live birth from a frozen human egg cell dates back to 1986, egg freezing has long been so inefficient that it was hardly considered a valid treatment option. From 2004 onwards, however, there has been an explosion in research directed at oocyte cryopreservation (OC), leading to successful slow freezing and vitrification protocols for human egg cells with high survival rates after thawing and with reassuring preliminary data on the health of the resulting offspring (Cobo et al., 2014). There are several applications for this new technology: donor egg banking, but also autologous egg banking. The latter was introduced in the context of oncofertility, so that women fearing premature infertility due to disease, gonadotoxic medical treatments or irradiation therapies could bank their eggs before irreversibly losing them.

Soon there was also an interest in storing eggs for women not faced with a medical condition leading to premature infertility, but for those approaching the natural boundaries of their reproductive lifespan while being unable to start a parental project, for example due to lack of a partner. However, whereas the introduction of OC for oncofertility was met with much enthusiasm and optimism, the expansion of the option of OC to healthy women did not incite the same reactions (Mertes, 2013). Both the European Society for Human Reproduction and Embryology (ESHRE) and the American Society for Reproductive Medicine (ASRM) initially denounced the use of OC for healthy women, while endorsing it for medical conditions. In 2012, ESHRE changed its recommendations, saying that OC should also be available for non-medical reasons, whereas the ASRM remains cautious (ESHRE Task Force on Ethics and Law et al., 2012; Practice Committee of the American Society for Reproductive Medicine and Practice Committee of the Society for Reproductive Technology, 2012).

Medical versus Social freezing: A Tenable Distinction?

A first important question is on which grounds a moral distinction can be made between “medical egg freezing” and “non-medical egg freezing”. If women are only allowed to preserve their fertility when they anticipate premature infertility, but not when they anticipate natural infertility, one needs to give a justification for this differential treatment. Several arguments are possible, but not convincing. A first one is that we should respect natural boundaries. But why? Is medicine not constantly interfering with the natural decline of our bodies? A second one is that only those who are unable to anticipate (and thus prevent) being infertile before embarking on parenthood are deserving of a medical intervention. But why? First, medicine is constantly curing preventable medical problems. Second, the “solution” of reproducing early in life is not an option for everyone: there are very good reasons for waiting to establish a family until certain side constraints are in place, such as having a partner, financial stability, et cetera.

Moreover, there is a large gray area between medical and non-medical reasons for egg banking. In which category do women who freeze their eggs due to a family history of early menopause (and a low ovarian reserve) belong? What about women who have undergone a cancer treatment in the past that has diminished, but not depleted their ovarian reserve and who want to store eggs after their treatment because they fear premature ovarian failure? In short, it is difficult to indicate what the crucial difference between the two applications (medical and non-medical) is and even more so why it would matter.

Reasons for Caution

Yet there are reasons to be cautious about the introduction of AGE banking, with the main fear being that this new technology is being “oversold”. [Cobo et al. \(2016\)](#) report cumulative live birth rates in women 35 or younger of respectively 15.4%, 40.8%, and 85.2% when freezing 5, 8 or 15 oocytes. The cumulative live birth rates achieved with 5, 8 and 11 oocytes for women 36 or older were 5.1%, 19.9% and 35.6% (in this group the additional benefit of banking more than 11 oocytes is very small). At present most women opting for AGE banking belong to the latter group, not the former, as reported average ages at the time of egg banking range from 36 to 38 years. Although these are good success rates compared to a subfertile population, this still means that most of these women have at best a 35% chance of achieving a healthy live birth (if their ovarian response is good enough to generate 11 oocytes). This contrasts with the image of egg freezing that commercial companies offering this technology create. Egg banking is said to “stop the biological clock” or offer “insurance” against infertility. The fear is that women will expect more of egg banking than the intervention can deliver and that many women will feel disappointed and betrayed when it turns out that the eggs they stored do not lead to a live birth. In this sense, an intervention that is being marketed as increasing women’s reproductive autonomy becomes an intervention that curtails reproductive autonomy and preys on desperate women.

Should this technology be marketed to young women then, with higher success rates? In fact, this may equally lead to an undermining of a woman’s intended reproductive life plan. When egg banking becomes a deliberate attempt to put parenthood “on hold” while other life goals are being pursued (possibly under pressure of employers), women may insufficiently be aware that egg banking in such a context jeopardizes a woman’s reproductive potential, rather than safeguarding it, as a woman’s chances of reproducing naturally at a younger age will always be better than her chances of reproducing with banked eggs at an older age. This fear became a lot less hypothetical when Facebook and Apple announced in 2014 that they would offer egg freezing to their female employees ([Mertes, 2015](#)).

What Does a Cautious Implementation Look Like?

The crucial question then becomes: how can this technology be implemented in a way that has maximal respect for reproductive autonomy and an acceptable utility rate? Regarding the utility rate the paradox is that the younger women freeze their eggs, the better quality the eggs will be, but the less chance that the woman will actually need them, as they have plenty of time to reproduce naturally. The older a woman is when she freezes her eggs, the worse their quality, but also the less chance she has of reproducing naturally (and the more chance to need her stored eggs). The ideal age for egg banking would therefore be between 30 and 35 ([Mertes and Pennings, 2011](#)). Also, women opting for egg banking should be counseled carefully about the drawbacks of AGE banking: about the success rates, tailored to their age/ovarian reserve; about the technicalities of the procedure, for example the fact that ICSI will be needed; about the maximal storage period, etc. Next to this practical counseling, it would also be beneficial to inspire candidates for AGE banking to critically reflect on the importance of (genetic) parenthood and on the prospect of the alternatives. This may imply that women approaching their forties or young women with many fertile years ahead of them will end up being discouraged from storing their eggs, while women who are most likely to benefit will be encouraged to bank. Given the possible biasing effect of commercial interests, it becomes increasingly important to ensure that counseling and information provision to women is as objective and complete as possible.

Stem Cell Derived Gametes

The in vitro creation of stem cell-derived (SCD) gametes promises new possibilities for human procreation, both via basic science applications and clinical use in assisted reproduction. The value of genetic relatedness is an important incentive in the development of this technique. Proof of principle for in vitro gametogenesis (IVG) is available in mice, and it is believed that the differentiation of functional human gametes from pluripotent stem cells will be possible in the “not too distant future” ([Cohen et al., 2017](#)). Creation of gametes from embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs) is the main focus. Other sources such as bone marrow stem cells and germline stem cells receive less (ethical) attention. We will first outline the possible reproductive applications of IVG and then the ethical challenges of both ESC-derived and iPSC-derived gametes.

Patient-Specific SCD-Gametes

The most important goal of IVG is to establish a genetic link between the parents-to-be and the future offspring. To establish a genetic link, patient-specific SCD-gametes are needed. This requires either the creation of a cloned embryo through somatic cell nuclear transfer (SCNT) from which ESCs are derived or the creation of induced pluripotent stem cells (iPSCs) from a somatic

cell of the patient, which will then be differentiated into gametes. It is also suggested that IVG would make equal genetic relatedness between the child and both partners possible for same-sex couples, but researchers remain skeptical about reprogramming stem cells to gametes of the opposite sex (Moreno et al., 2015). Moreover, if IVG is to lead to the creation of patient-specific SCD-gametes at all, the technique of SCNT or the technique to obtain iPSCs would have to be improved.

If it would become possible to create patient-specific SCD-gametes, it could also be combined with technologies to prevent certain diseases in the future offspring. IVG could enable the creation of a large gamete and embryo pool to select (through PGD) genetic traits. Alternatively, stem cells could be modified via genome editing, and then differentiated into gametes (Vassena et al., 2016). This can be seen as an additional benefit, although it also raises concerns about possible usage to select/edit non-disease related traits.

Non-Patient-Specific SCD-Gametes

Deriving gametes from ESCs of embryos created by fertilization is presumably more feasible and closer to clinical application than creating patient-specific SCD-gametes. This would require the use of donated spare IVF embryos, or embryos created from oocytes and sperm donated for this goal. However, these gametes would be non-patient-specific, and will thus not lead to shared genetic parenthood.

Yet, the value of parent-child genetic relatedness also plays a central role here. Non-patient-specific SCD-gametes could be used to create an SCD-gamete bank for “third party” assisted reproduction. One benefit of this scenario over “traditional” donor assisted reproduction is that the parents-to-be would not have to fear that the donor would claim parental rights based on his/her genetic link with the child, since the donor (the embryo) is destroyed in the process of gamete derivation (unless such rights would be accorded to the genetic grandparents, viz. the embryo donors). Also, the resulting child would have no “unknown” genetic progenitor to look for, which might be more comforting than knowing that one’s genetic parent is “out there”. It could, however, be countered that this benefit is undermined by the child’s inability to enrich his/her narrative by knowing that one of his/her genetic parents never existed as a person.

Non-patient-specific SCD-gametes could also be used for same-sex reproduction: a gamete derived from a fertilized embryo, created by combining a donor gamete with one of the partner’s gametes, could be combined with the other partner’s complementary gamete (Segers et al., 2017b). This would lead to a 50% genetic link between the latter partner and the child, while both the other partner and the donor would share 25% of the child’s DNA. Many would consider it an important advantage of this scenario that although a donor is still involved, it will not be possible to ascribe a greater parental status to him/her solely on the basis of his/her genetic contribution. The partner who contributed as much to the child’s genetic makeup as the donor, would outrank the donor given his/her role as a social parent and the intention to be a parent.

New Possibilities of Reproduction

Application of IVG for reproductive purposes could revolutionize human procreation. Apart from possible use in same-sex reproduction and treatments for infertile couples of reproductive age, IVG could allow anyone to produce gametes, regardless of age or relationship status (Smajdor and Cutas, 2015). If person-specific gametes could be created from stem cells, this could allow women to reproduce later in life, despite declining oocyte quality and even if they have already gone through menopause (see above). Prepubescent children would not be restricted by their age to have genetically related offspring either. IVG could also allow variations in the number of people involved in genetic parenting. Fusing someone’s natural gamete with a derived gamete from this same person could result in single genetic parenthood. Also multiple genetic parenting might become possible: gametes of multiple persons could be combined to create embryos, from which ESC-derived gametes could be established, which could again be recombined in as much cycles as needed to obtain a child who is genetically related to each of the participating persons. For a more extensive ethical discussion of these scenarios, see: Smajdor and Cutas (2015) and Segers et al. (2017a). In the final section, we will explore some of the general ethical concerns about IVG.

Main Ethical Concerns

For reproductive IVG, the main ethical issue is the safety risk to the offspring. At this stage, clinical application of IVG is unacceptable because of the potential high risk to the offspring’s physical wellbeing. This is especially the case for patient-specific SCD-gametes, as both the technique of SCNT and that of iPSCs derivation are hindered by incomplete reprogramming of the somatic cell nucleus to an embryonic state. The derivation of gametes from ESC-lines from embryos created by fertilization would be less complicated and therefore possibly safer. Still, this raises the question what standard of risk is acceptable to make genetic relatedness possible, or, in the case of non-patient-specific reproductive IVG, to avoid the attribution of parental status to the donor. It could be argued that, unless their life is not worth living, IVG offspring cannot be harmed by the parental choice to reproduce through IVG because without this decision they would not have existed at all. However, this conclusion runs counter to most people’s moral intuition. Instead the “reasonable welfare principle” has been suggested: this standard is adopted by the European Society of Human Reproduction and Embryology (ESHRE) and holds that the use of a reproductive technology is only acceptable if the resulting child will have a reasonably happy life (Pennings et al., 2007).

Even if IVG would be safe, it is worth contemplating that the endeavor of creating SCD-gametes for reproduction might reinforce the dogma of genetic relatedness. Even the use of non-patient-specific SCD-gametes could, at least implicitly, propagate the importance of genetic ties in a parent–child relationship. This is not morally wrong per se, and is also not unique to IVG, but it could send the incorrect message that a good parent–child relationship requires a genetic link. According to this reinforcement argument, IVG would create rather than meet demand, which is a fortiori important given the related questions of access, cost and resource allocation. Because IVG will probably not be affordable for everyone who could benefit from it, it could be argued that access to IVG should be state covered. It is questionable, however, whether the goals that are served by IVG are important enough to outweigh other claims on public resources. When this weighing is done, not only the goal of reproduction should be considered, but also the possible benefits of IVG in the research context.

A final argument is that IVG as such is unacceptable because it inherently involves embryo destruction. Embryo destruction is obvious if ESC-derived gametes are used (both patient-specific and non-patient-specific), but also the iPSC route might be troubling for those who oppose embryo destruction. While iPSC-derived gametes generally avoid the use of embryos, embryos will still have to be created in the research phase to ensure the safety of the technique. Many people find it less disrespectful to use spare IVF embryos (as they will be destroyed anyway), but those applications involving the destruction of embryos created from SCD-gametes that were differentiated from spare embryos will likely be opposed by those who object to the intentional creation/destruction of embryos. Only if the prohibition of embryo destruction is not regarded as an absolute rule, and if the importance of the goals of IVG (whether reproductive or scientific) outweigh the cons of creating and destroying embryos, can those who oppose embryo destruction accept IVG in general.

Conclusion

Having a genetically related child is a highly valued goal in many people's lives. Still, it is not easy to justify as the benefits of this wish are unclear. When the wish is accompanied by possible health risks for the offspring, society and the future parents will have to decide what risk is acceptable. In this balancing act, the existence of alternatives has to be taken into account. Donor gametes are such an alternative in most circumstances. However, this solution is more complicated from the psychosocial point of view given the increasing value attributed to genetic relationships.

Abbreviations

3D	3-Dimensional
ART	Assisted reproductive technology
EDC	Ethylcarbodiimide
eMSC	Mesenchymal stem cell-like stem cell source from the endometrium
ES	Embryonic stem
GFP	Green fluorescent protein
iPS	Induced pluripotent stem
MRKHS	Mayer-Rokitansky-Küster-Hauser syndrome
MSCs	Mesenchymal stem cells
NHC	Hydroxysuccinimide
SMC	Smooth muscle cells
STAT3	Signal transducer and activator of transcription 3

The Concept of Bioengineering

Bioengineering, or tissue engineering, is a research discipline in regenerative medicine that combines various types of cells and materials for the production of implants/grafts with the purpose to restore or improve tissue function. The largest fields within the bioengineering discipline are indisputably bone- and skin regeneration. However, cardiovascular-related tissue engineering solutions are also comprehensively investigated, e.g., for heart valves and blood vessels.

The discoveries of adult stem cells (both of hematopoietic- and of mesenchymal stem cell origin) in the 1960s generated a vast interest to harvest, grow and utilize these cells for various cell-based therapies and together with various biomaterials to improve construct function and adaptation after implantation. For example, mesenchymal stem cells (MSCs) have been used extensively due to their ability to participate in tissue repair and regeneration, and due to their unique immunomodulatory properties that reduces the host foreign body response to the biomaterial ([Hanson et al., 2014](#)). There is a large quantity of MSCs that resides in the bone marrow, but MSCs can be harvested from a wide variety of adult tissues which makes them attractive to use as a cell source for the generation of a patient-specific transplant. Other sources of mature cell types can be used, however the versatility of MSCs differentiation (e.g., they can mature into hard- or soft tissue cell types) and their ability to proliferate, usually surpass any other adult cell type contender. MSCs can be isolated directly from the patient, expanded and/or differentiated in vitro, and then be transplanted for the therapeutic purpose without causing a significant immune response. Other cell sources that are interesting to use for bioengineering is embryonic stem (ES) cells or induced pluripotent stem (iPS) cells. The use of ES cells is attractive since they have an ability to differentiate into any kind of adult tissue. However, there are some limitations since they are; (a) difficult to control and direct into the correct cell lineage, (b) known to cause cancer-like teratomas, (c) ethically debatable since they are of fetal origin, and (d) not patient-specific and may thus activate an immune response following transplantation. iPS cells are perhaps therefore a better cell source than fetal stem cells to use for bioengineering. iPS cells can be constructed by reprogramming adult cells taken e.g., from a skin biopsy. By inducing an overexpression of various transcription factors (e.g., the Yamanaka factors; Oct3/4, Sox2, cMyc, and Klf4), the cells are manipulated to reverse their differentiation state. These immature cells can then be used to generate many different tissue-specific cell types ([Takahashi and Yamanaka, 2006](#)). This discovery gave Dr. Yamanaka the Noble price in 2012. Thus, iPS cells can be used to create patient-specific bioengineered grafting material which would be immune tolerable after transplantation. However, the potential of iPS cells, and possible risks involved are still relatively unknown in the clinical setting.

Bioengineering for Reproductive Tract Disorders

Reproductive tract disorders and infertility often lead to substantial socio-psychological distress. These conditions may be acquired from birth (e.g., Mayer-Rokitansky-Küster-Hauser syndrome; MRKHS) or may be disease-induced (e.g., testicular infection, uterine fibroids or salpingitis) or consequences from treatments (e.g., chemotherapy- or radiotherapy induced sterility, hysterectomy or oophorectomy). While in some of these conditions, fertility can be established with standard assisted reproductive technology (ART), other conditions lead to permanent infertility. However, novel research that evaluates bioengineering solutions in animal studies may one day lead to new treatment protocols for these patient groups. These ideas include the use of grafted engineered tissues that facilitates sperm motility (vas deferens), sexual intercourse (corpus cavernosum; vaginal reconstruction), give growth support to maturing follicles (artificial ovaries), stabilizes the pelvic region using bioengineered meshes for prolapse treatment, or to a uterine wall defect during pregnancy (uterine tissue patches), or even the creation of a transplantable whole bioengineered uterus that may be able to replace a donor in a uterus transplantation setting ([Sadri-Ardekani and Atala, 2015](#); [Campo et al., 2017](#); [Hellström et al., 2017](#)).

Stem Cells for the Creation of Gametes

Different sources of stem cells have been used to create sperm cells for potential use in fertility treatments, both on animal- and human cells. For instance, spermatogonial stem cells can be harvested from the basement membrane of the seminiferous tubules in the testis, and are the origin of spermatogenesis. These cells can either be derived into mature and functional sperm cells in vivo (by re-transplantation) or by in vitro differentiation. These methods resulted in matured sperm cells successful of oocyte fertilization that led to offspring in zebra fish, mice and rats ([Hendriks et al., 2015](#)). Sperm cells were also derived from in vitro differentiated iPS cells, including human cells. However, due to ethical- and legal reasons, this work has not yet lead into any human births. These ideas however, may become future treatment options for sterile men where standard ART is unsuccessful. It is important to mention that alterations in the genome, or the epigenome may occur during the reprogramming ([Eguizabal et al., 2011](#)), thus rigorous testing should precede any clinical protocols.

Similarly, adult female cells (iPS cells) and stem cells (embryonic- and oogonial stem cells) were reprogramed and differentiated into oocytes ([Hendriks et al., 2015](#)). As for cancer treated young men, young women also risk sterility due to the negative side-effects from cancer treatment. These patients may benefit by cell reprogramming. However, this is a controversial topic since artificial oocytes also have been derived from male cells, and artificial sperm was created using a female cell source ([Hendriks et al., 2015](#)).

Bioengineering in the Male Reproductive Tract

Genitourinary tract abnormalities sometimes require surgical interventions, but sufficient autologous tissue for the reconstruction is often limited. For these reasons, a rabbit model was used to evaluate the construction of bioengineered corporal tissue derived from a biodegradable polymer scaffold which was seeded with corporal smooth muscle cells (SMC) and endothelial cells ([Chen et al., 2010](#)). Results from in vivo studies showed significantly more sperm after native mating, and only the treated animals were able to generate offspring. In another successful rabbit study, an obstructed vas deferens was repaired using tubular shaped encapsulated autologous myofibroblast-rich tissue ([Campbell et al., 2008](#)). These reports show the potentials of using bioengineering solutions for novel treatments of male reproductive tract disorders. However, more follow-up studies are required, including on larger animal models to evaluate the usefulness and safety of such constructs prior any clinical use.

Bioengineering in the Female Reproductive Tract

Ovarian Bioengineering

Fertility preservation methods for cancer treated women were successfully developed by Professor Donnez and his colleagues. Before the fertility-detrimental radio- and chemotherapy, fertility may be preserved in female patients by an ovarian cortex cryopreservation and a re-transplantation procedure. More specifically, the follicle-containing ovarian cortex can be isolated by minimal invasive laparoscopy prior to cancer treatment, and then cryopreserved in small rectangular tissue pieces which can be re-transplanted back to the patient after the successful cancer treatment. Thus, the patient re-acquires a part of her original follicle reserve that may otherwise have been lost due to the radio- and chemotherapy. Hormone production and oocyte maturation have shown to be reestablished and this method has now generated more than 100 healthy babies around the world ([Donnez and Dolmans, 2015](#); [Chiti et al., 2017](#)). However, this method cannot safely be performed on patients treated for blood-related cancers since they risk reintroducing the malignancy along with the cryopreserved ovarian tissue. Therefore, scientists now evaluate bioengineering solutions to support the growth of isolated early follicles. The advantage of transplanting isolated follicles rather than the ovarian cortex is that they do not contain any blood-related cancer cells and could therefore potentially be transplanted safely back to the treated patient.

Biomaterials made of various hydrogels (e.g., based on fibrin and/or alginate) work particularly well for ovarian bioengineering protocols in rodents. Multiple groups witnessed follicular maturation using such constructs and succeeded with the generation of healthy offspring using harvested functional oocytes from these grafts (Chiti et al., 2017). However, it is particularly challenging to construct an ovarian biomaterial suitable for human folliculogenesis since the volume of the primordial human follicle expands about 4.7×10^6 -fold before reaching the final mature stage of a follicular diameter of about 20 mm. Similar follicular expansion is seen in many other large mammals, which can be compared to the much lesser expansion seen in rodents (with an estimated 37-fold volume expansion) (Shea et al., 2014). During folliculogenesis, the biomaterial needs to be plastic enough to allow the expansion to occur, yet give structural support to the follicle to prevent collapse. Thus, improved biomaterials need to be developed. Lately, scaffold production through a method called decellularization received a lot of attention in the bioengineering field. This method is based on normal tissue which has been stripped from cells thorough a series of washing procedures. The remaining structure consists of tissue-specific extra cellular matrix low on immunogenic components that has the 3-dimensional (3D) shape of the original organ. Thus, this structure offers a biologically-based biomaterial that may avoid a negative immune response after transplantation and new cells should recognize it and be able to remodel it as required. This prospective biomaterial is only just starting to be evaluated for ovarian bioengineering applications (Laronda et al., 2015; Liu et al., 2017). An alternative to fibrin/alginate-, or to use decellularized tissue as an ovary scaffold is to use a 3D-printed construct. Recently, follicles isolated from green fluorescent protein (GFP) mice were applied to a 3D-printed gelatin scaffold crosslinked with an ethylcarbodiimide (EDC)-hydroxysuccinimide (NHC) solution. These follicles underwent successful folliculogenesis and matured oocytes could successfully be fertilized resulting in GFP-fluorescent mice pups (Laronda et al., 2017). When an improved ovarian-like biomaterial has been developed that can provide support to the vast follicular expansion required for larger mammals, a rapid progress to reach the clinic is expected.

Bioengineered Meshes in Pelvic Prolapse Surgery

Pelvic organ prolapse that results from childbirth affect up to 25% of all women and significantly reduces their quality of life. Current treatment protocols for severe pelvic organ prolapse include using meshes to surgically stabilize the pelvic region. However, about 15%–30% of these treatments fail and common problems include pain and mesh erosion into the bladder, vagina or bowel. Therefore, it has been proposed to use MSCs as a mean to improve the meshes biocompatibility (Emmerson and Gargett, 2016). Due to the MSCs' immunomodulatory and antiinflammatory properties, it may be advantageous to coat the meshes with these cells prior to implantation. Indeed, rodent studies using an MSC-like stem cell source from the endometrium (eMSC) proved beneficial (Ulrich et al., 2014). Ongoing studies on large domestic animals (ovine) will further examine if bioengineered meshes coated with autologous eMSCs can lead to clinical improvements in the near future (Emmerson and Gargett, 2016).

Partial Uterus Reconstruction

The existence of uterus-resident stem cells and the fact that the endometrium is a highly regenerative tissue may enable novel bioengineering applications to the uterus. Partial uterine repair may become clinically applicable and a desired treatment regimen since the prevalence of caesarean delivery is increasing resulting in significant uterine wall scarring. Similar injury also results from repeated uterine surgeries due to extensive myomectomy, adenomyomectomy or from resection of placental tumors. The creation of a bioengineered patient-specific uterus patch to cover/replace uterine scars may in these cases be used to increase the strength of the uterine wall. Uterine bioengineering could thus become a major advantage for the many women that otherwise risk life-threatening adverse pregnancy complications. Multiple groups reported progress in uterine tissue reconstruction using various semi-synthetic- and biological biomaterials (Campo et al., 2017; Hellström et al., 2017). For example, scaffold matrixes made up of collagen/matrigel, or collagen/silk were evaluated in vitro using static cell culturing methods with mouse-, rabbit- or human cells. These scaffolds allowed for some diffusion of the culture media into the deeper layers of the constructs which enabled the formation of a stratified morphological structure, similar to that of a normal uterine wall.

Decellularized tissues as extra cellular matrix scaffolds for uterine tissue have also been evaluated. Scaffolds created by decellularization provide some general advantages over synthetic scaffolds, for example they; (a) consist of the correct tissue specific extra cellular matrix composition, (b) have the physical 3D appearance of the original organ with the correct architecture for blood vessels and glandular ducts, (c) allow cells to be reintroduced and sustained in a perfusion bioreactor via the vascular conduits for organ regeneration, (d) can be remodeled by repopulated cells, and (e) provide guiding cues for tissue specific cell differentiation and migration (Fig. 1) (Crapo et al., 2011). For uterine tissue reconstruction, patches of decellularized rat- and human myometrium was first described (Young and Goloman, 2013). These protocols were developed using ethanol- and trypsin as cell removal agents, and then the scaffolds were re-seeded with human or rat myocytes. After about 50 days, coordinated contractions from the bioengineered tissues were noticed, suggesting some biological function. Santoso et al. showed that decellularized rat full-thickness uterus patches could be decellularized and then used as grafting material (without prior cellular reconstruction) (Santoso et al., 2014). Later, the same group members used the mouse model to show that the spontaneous tissue regeneration in the grafted area was Signal Transducer and Activator of Transcription 3 (STAT3) -dependent and estrogen- and progesterone independent (Hiraoaka et al., 2016). Recently, slices of human endometrium were decellularized and then reconstructed again using primary endometrium cells (Olaekan et al., 2017). This in vitro recreated endometrium was viable for up to 28 days and responded to hormonal stimuli. Collectively, these studies provide important clues on how to best create engineered constructs for partial uterine repair.

Fig. 1 The normal rat uterus (A) can be decellularized by perfusing detergents and other solutions through the vasculature (B). Including multiple washing procedures, this process takes about 5–10 days depending on the type of chemicals used.

Furthermore, they may also aid towards the development of a bioengineered whole-uterus that potentially could replace the need for a donor in a uterus transplantation setting.

Uterus Transplantation and Whole-Uterus Bioengineering

The pioneering work that led to the world's first baby born from a transplanted uterus started in 1999 by Professor Brännström's team on small animal models. As successful surgery techniques with proof-of-function were established, the team rapidly progressed to larger animal models that included pig, sheep and nonhuman primates. This translational research approach led to the successful clinical trial that began in 2013 that included nine female uterine factor infertile patients (eight with MRKHS, and one with previous hysterectomy) (Brännström, 2017; Brännström et al., 2015). Two of the patients had their grafts removed due to an infection and a thrombosis, respectively. However, today, 6 babies have been born and there are two ongoing pregnancies (week 34) from a total of 7 patients who received embryo transfers. This trial used live donors, and this may be one of several reasons for the successful outcome, since multiple centers have now begun uterus transplantation trials using diseased donors with less successful outcomes (reports from open media). The live donor approach has some major advantages, including; (a) the ability to choose a donor uterus with proven functionality, and (b) logistically advantageous to better prepare the donor- and recipient surgeries and minimize cold ischemic injuries. However, the risky donor surgery is challenging and is considerably long with an average of about 12 h (Brännström et al., 2014). Furthermore, the recipient needs pharmacological agents to suppress probable immune rejection events following the engraftment, and thus risk negative side effects such as accelerated arteriosclerosis, nephrotoxicity, hypertension, diabetes and reduced fertility. The possibility of creating a bioengineered patient-specific donor organ instead of using a live donor would eliminate these risk factors (Hellström et al., 2017).

For these reasons, protocols for whole uterus decellularization were developed, first on the rat (Hellström et al., 2014; Miyazaki and Maruyama, 2014), and then more recently also on the pig (Campo et al., 2017). In these reports, the uterus was efficiently decellularized by perfusing combinations of hyper- or hypotonic solutions and detergents through the organ's vasculature. Detailed analyses on the remaining uterus ECM scaffolds showed that the developed scaffolds were rich in collagen, elastin, fibronectin and other important ECM biomolecules (Fig. 2). Importantly, these perfusion procedures also maintained patent conduits for the vasculature (Hellström et al., 2014; Miyazaki and Maruyama, 2014), even down to the small capillaries (Campo et al., 2017). This enables anastomoses and future re-transplantation, including vascular anastomoses of the bioengineered uterus. Toxicity- and biocompatibility tests on these scaffolds were conducted by recellularization studies which showed that cells can attach and survive, but that the cell distribution was mainly limited to the peripheral parts of the scaffold, or in isolated pockets within the deeper layers (Hellström et al., 2017). When rectangular patches of the reconstructed rat uterus scaffolds were cut out and transplanted into a rat model

Fig. 2 The normal rat uterus is densely cell-populated as viewed here by scanning electron microscopy (A). Depending on the chemicals used for decellularization, the remaining porous structure (B) consists of tissue specific extra cellular matrix, rich in collagen, fibronectin, elastin and other important macromolecules that support cell growth (C). *p*, perimetrium; *m*, myometrium; *e*, endometrium; *l*, lumen.

with an impaired uterine wall, these patches showed to improve the healing and regeneration. Pregnancies were also reported from the operated animals, some fetuses even growing in the graft-area (Hellström et al., 2017; Miyazaki and Maruyama, 2014). This confirms that the constructs are strong enough to support full-term pregnancy. However, no placentation has yet been reported over the graft itself. This would have proved the functionality of the bioengineered constructs with respects to successful implantation and embryogenesis. Nevertheless, collectively these studies show great potential using uterine tissue engineering for partial uterus reconstruction, but additional animal studies are required to further optimize methods which can generate transplantable bioengineered whole-uterus constructs able to be grafted along with vascular anastomosis.

Conclusions

The production of an artificial ovarian structure that supports folliculogenesis as a mean to preserve fertility for young cancer treated women has shown great promise in studies on the mouse. Particularly when using biomaterials such as alginate, fibrin and 3D-printed gelatin. When improved scaffolds have been developed that can support the prominent follicular expansion characteristic to larger mammals, a rapid progress towards clinical use is expected.

Perhaps a more debatable route to preserve fertility includes using reprogrammed somatic cells, or isolated germ cells. These methods show potentials to one day offer fertility solutions to conceive genetically related children to sterile men and women. However, the overexpression of transcription factors and the re-differentiation procedures that takes place in an artificial in vitro environment has yet to be proved safe, also considering potential epigenetic changes.

Bioengineered uterine tissue patches have proved beneficial to repair and increase fertility in rats with a full thickness uterine wall injury. This rapid and promising progress in using bioengineered uterine patches in rodents show that the field is ready to move forward and evaluate these strategies in large animal models to see if these treatment regimens are translational to a clinical setting. However, large bioengineered patches need to be assessed further. This research will also contribute to the development of a whole bioengineered uterus that could possibly provide a major advantage for both the donor and the recipient in a uterus transplantation setting. So far, limitations in the reconstruction phase of the scaffolds need to be resolved. Improved recellularization is dependent on the scaffold composition, what cell types are used, how the cells are added to the construct, and under what conditions the recellularized scaffold is cultured in vitro. All these factors need further optimization to improve the outcomes of uterus bioengineering experiments.

Acknowledgments

The author thanks Professor Mats Brännström for correcting the manuscript and for the continuous research support. The author also acknowledges the Centre for Cellular Imaging at the University of Gothenburg and the National Microscopy Infrastructure, NMI for providing assistance in the scanning electron microscopy. This work was supported by Hjalmar Svensson-, Adlerbertska- and the Wilhelm och Martina Lundgrens Research Foundation, and the Swedish Science Research Council (Vetenskapsrådet; Grant No. 116008).

Introduction

The endometrium is a tissue with a high capacity for renewal ("self renewal") regulated by hormones that undergoes almost complete changes of growth, differentiation, and shedding every 28 days during 400–500 cycles during a woman's reproductive life-time. This level of tissue regeneration is comparable to other high cellular turnover tissues such as the epidermis, gut epithelium, and/or bone marrow.

The biology of the menstrual cycle involves the hypothalamus, pituitary, ovary and finally the endometrium in a coordinated and complex sequence. During the menstrual phase, the endometrium undergoes changes and is sloughed in women due to a drop in progesterone and estrogen levels. The proliferative phase is defined as the period of time from the menstrual phase to ovulation. As estrogen levels begin to rise, the endometrial lining thickens leading to a proliferative pattern. Estrogen (spell the same way thru the article) triggers a proliferation of stroma and glands and elongation of the spiral arteries. The secretory phase corresponds from ovulation to through menstruation. After ovulation, progesterone levels rise in the early secretory phase which leads to the secretion of glycogen and mucus. In the mid-secretory phase, the endometrium becomes decidualized and receptive for a fertilized embryo to implant. Finally, in the late secretory phase, in the absence of pregnancy there is a drop in both estrogen and progesterone levels which causes the spiral arteries to vasoconstrict, leading to involution of the endometrium and menstruation.

Histologically, the endometrium is divided in two functional layers: the basal and functional layers. The functional layer responds to progesterone and estradiol and is completely shed during menstruation. On the other hand, the basal layer does not respond to hormones and also does not undergo desquamation and is responsible to regenerate the mucosa. The human endometrium is composed primarily of two main cell types, epithelial cells (luminal and glandular) and supporting mesenchymal cells (stromal cells). In addition endothelial cells and leukocytes are found within the endometrium. The endometrial–myometrial junction is irregular with no submucosal tissue to separate endometrial glandular tissue from the underlying smooth muscle of the myometrium. The ultimate function of the endometrium is allowing an embryo to implant. However, implantation is not an efficient process and natural conception rate in healthy young couples is only about 25% per cycle. Inadequate uterine receptivity seems to play an important role in these cases of implantation failure (Simon and Laufer, 2012).

An increasing number of studies which constitute the current knowledge about endometrium-derived stem cells (EDSCs) have been published in the last decade. These studies support the fact that stem cell play a significant role in the highly regenerative self-renewal capacity of the endometrium. These stem cells functions are regulated by the niche which is defined as the specific physiological microenvironment in which niche cells secrete molecules to regulate stem cell proliferation and cell fate decisions according to the tissue needs. The niche is crucial to maintain a correct homeostasis of the tissues and is mostly placed in the basal layer (Schwab and Gargett, 2007; Cervello et al., 2010) of the endometrium which is mostly vascularized by the spiral arteries. Moreover,

some endometrial stem cells reside in the functional layer of the endometrium next to the blood vessels in form of pericytes. In this sense, some groups have reported the presence of stem cells in menstrual blood.

A subgroup of cells with adult stem cell activity in the human endometrium have been described in the endometrium with capacity to differentiate into cell types of the three different germ layers such as chondrocytes, neurons (Wolff et al., 2011) and insulin-producing cells (Santamaria et al., 2011) that may contribute to the rapid endometrial regeneration following menstruation.

Bone marrow derived stem cells (BMDSCs) also contribute to the repair and regeneration of tissues and organs including murine and human endometrium (Du and Taylor, 2007; Cervelló et al., 2012; Ikoma et al., 2009). According to these findings, BMDSCs have the capacity to differentiate into fully functional stromal and epithelial endometrial cells. However, the BMDSC subpopulation(s) that promote(s) the repair of the endometrium remains unknown. Other studies have reported endometrial cells with a side population (SP) phenotype (that is, cells identified as having the capacity to extrude the DNA-binding dye Hoechst via the ATP-binding cassette transporter G2 (ABCG2) and that generally have a stem cell-like phenotype) that contribute to human endometrial regeneration in vitro and in vivo in animal models and human patients suggesting two different sources of stem cells: one endogenous source composed by resident endometrial stem cells and an other exogenous source composed by BMDSCs (Cervelló et al., 2012).

Certain pathological entities such as Asherman syndrome (AS) and endometrial atrophy (EA) share a common pathophysiology: the absence of functional endometrium that leads to infertility. Therefore, stem cell therapies targeting the endometrial niche with the ultimate aim to improve endometrial function may offer a promising possibility for treating AS and EA and participate in the regeneration of this pathological endometrium.

Asherman's Syndrome (AS) and Endometrial Atrophy (EA)

Asherman's syndrome (AS) is considered an acquired condition defined by the presence of intrauterine adhesions (IUAs). AS results when the bona fide endometrium is replaced with fibrotic tissues, causing the uterine walls to adhere to one another. This leads to symptoms such as menstrual abnormalities, pelvic pain, recurrent miscarriage, infertility, abnormal placentation and attendant psychological distress. The term AS should be applied when the signs and symptoms are present in women with established intrauterine adhesion although currently may be used only referring as intrauterine adhesions/scarring, synechiae or Fritsch syndrome (Zupi et al., 2015) indistinctly.

The prevalence of AS can vary significantly in different countries. This is because gynecological interventions may be a causative factors and in certain countries where gynecological care is not state of the art (for example, use of sharp, blunt or suction curettage for puerperal and postabortal evacuation) or where illegal interventions (for example, abortions) are performed at a higher frequency and/or to a lesser standard than in industrialized countries. In addition, other causative factors such as genital tuberculosis may also have a higher prevalence in some countries.

According to the European Medicines Agency (EMA), a rare disease has a prevalence lower than 5 out of 10,000 individuals. AS is included in the Orphanet database under the registry ORPHA137686, although the quality of the available epidemiological data are poor and the incidence and prevalence of are difficult to calculate. Recently the European Medicines Agency (EMA) has considered the prevalence of AS to be 4.4 cases/10,000 in the European Population (Committee for Orphan Medicinal Products, 2011). Danish studies and epidemiological public databases such as DESTATIS that provide information about the diagnosis in all the German hospitals support this prevalence.

Histologically, in AS the stroma is largely replaced with fibrous tissue and the glands are replaced by inactive cubocolumnar endometrial epithelium. The functional and basal layers are indistinguishable with the functional layer replaced by an epithelial monolayer unresponsive to hormonal stimulation and fibrotic synechiae forming across the cavity. The tissue is typically avascular, although thin-walled telangiectatic vessels can be observed.

Sometimes calcification can occur in the stroma and the glands may be cystically dilated. Different layers of the endometrium, myometrium or connective tissue may be involved in the resulting intrauterine adhesions. In the most severe cases, adhesions may be composed of collagen bundles, fibrous strips, or muscle with the same characteristics as normal myometrium. Biopsy specimens from patients with intrauterine adhesions compared with patients without intrauterine adhesions contain 50%–80% of fibrous tissue compared with 13%–20% in the uterine wall. This scarring limits uterine myometrial activity and reduces the perfusion of sex steroids resulting in atrophy.

Hysteroscopy is considered as the gold standard for diagnosis of AS and provides a real time view of the uterine cavity, allowing for a meticulous definition of the site, extent and character of any adhesions, and it is the optimum tool for assessing the endometrium. Currently, this technique can be performed in ambulatory setting with less discomfort than a HSG and also makes immediate treatment possible in some favorable cases (Conforti et al., 2013). Moreover, the magnification and the direct view of the adhesions allow for precise and safe therapy.

Fertility restoration after hysteroscopic treatment seems to be influenced by several factors such as menstrual pattern before and after the surgery, severity of adhesions and adhesions recurrence rate after treatment. An overall pregnancy rate from 40% to 63% was previously described and pregnancy rates ranged between 66% to 30%–35% in moderate to severe cases of AS in two prospective trials. Moreover, other retrospective studies have reported similar pregnancy rates for moderate and severe cases (Zikopoulos et al., 2004; Capella-Allouc et al., 1999; Pistofidis et al., 1996).

In addition to reduced fertility, other reproductive consequences of AS include recurrent miscarriage, intrauterine growth restriction, and placenta accreta.

Due to the possibility of adhesions recurrence, several different methods to prevent re-scarring after surgery for AS have been used, especially in cases of severe adhesions since a high rate of reformation of adhesions has been reported. Estrogen supplementation after surgery, or other additional therapies such as the insertion of intrauterine device (IUD), intrauterine balloon, hyaluronic acid among others has also been proposed. However, studies have not yet confirmed the method of treatment that is most likely to prevent recurrences and restore fertility.

On the other hand, endometrial atrophy (EA) is another rare condition in which the endometrium is too thin and unable to grow above 5–6 mm thickness (Senturk and Erel, 2008). Factors that can cause EA include functional (and usually reversible) causes such as prolonged use of oral contraceptives and tamoxifen, premature ovarian failure or Kallman Syndrome, but in many instances the cause of EA are unknown. The prevalence of this pathology is 0.5% of infertile women undergoing assisted reproductive treatments (ARTs). Patients suffering EA patients have a poor reproductive outcome despite many therapies have been attempted such as high doses of estradiol therapy, pentoxifyline and vitamin E, sildenafil, L-arginine or intrauterine perfusion of Granulocyte Colony Stimulation Factor (G-CSF). None of these treatments has proved to be fully effective.

Research related to endometrial stem cells is relevant to understand normal endometrial physiology. Novel stem cell based approaches may prove to be very useful for both EA and AS.

Regenerative Medicine

The endometrium has an intrinsic capacity of regeneration that normally occurs after menstruation or delivery. As previously explained, there is substantial evidence in literature that adult endometrial tissue contains epithelial progenitor cells and mesenchymal/stromal (MSC) cells. The niche of these stem cells could be the target of a specific therapy in order to regenerate the endometrial tissue in cases of dysfunctional/nonfunctional or atrophic endometrium. Therefore, stem cell therapy offers an attractive alternative to the treatment of these pathological conditions aiming to regenerate the endometrium. In this sense, several studies have evidenced the potential benefit of regenerative therapies in AS and EA. A case report of a severe AS treated with autologous stem cells isolated from the women's own bone marrow was firstly described (Nagori et al., 2011). The case consisted in woman with history of infertility and hypomenorrhea and that had been previously hysteroscopically treated for severe intrauterine adhesions with an IUD placed inside the uterus for 6 months. During that time, she also received therapy with combined estrogen and progesterone (ethinylestradiol and medroxyprogesterone). Finally, after failure of hormonal therapy in restoring endometrium, endometrial stem cells were implanted inside the uterus after curettage on the second day of menstrual cycle. A clinical pregnancy was obtained after a heterologous embryo transfer.

Our group performed a proof of concept study using CD133+ BMDSCs demonstrating that in the first 3 months, autologous cell therapy, using CD133+ BMDSCs in conjunction with hormonal replacement therapy, increased the volume and duration of menses as well as the thickness and angiogenesis processes of the endometrium while decreasing intrauterine adhesion scores. In this study functionality of the treated endometrium revealed pregnancy rates of 50% and five live-births out of four uncomplicated pregnancies.

Background on Stem Cell Therapy

Stem cells are undifferentiated cells with the ability to proliferate into undifferentiated cells both in vitro and in vivo (self-renewal) and to differentiate into mature specialized cells (43). Many adult tissues contain populations of stem cells that have the capacity for renewal after trauma, disease, or aging. The cells may be found within the tissue or in other tissues that serve as stem cell reservoirs. Embryonic stem cells, induced pluripotent stem cells, hematopoietic stem cells, and mesenchymal stem cells have been used to derive mature cell types for tissue regeneration and repair.

Adult bone marrow represents an important reservoir of stem cells including vascular progenitor cells. These stem cells from the bone marrow have the capacity to express different biomarkers including CD133/VEGFR2 which represent a subpopulation of cells with endothelial progenitor capacity and are known as EPCs. Furthermore, these cells can be mobilized to the peripheral circulation as circulating endothelial progenitors (CEPCs) and participate and improve neoangiogenesis afforded by preexisting endothelium as shown in different physiological and pathophysiological processes such as wound healing and limb ischemia, postmyocardial infarction, endothelialization of vascular grafts, atherosclerosis, retinal and lymphoid organ neovascularization, vascularization during neonatal growth and tumor growth. Additionally, CD133+ have the capacity to differentiate into nonhematopoietic cell lineages and display long-term repopulation potential in SCID mice (Rafii and Lyden, 2003).

Certain bone marrow derived stem cells have the capacity to engraft and fully differentiate into the endometrium as observed in the endometrium of women who had previously undergone a bone marrow transplantation of a HLA mismatch or male donor (Ikoma et al., 2009; Taylor, 2004).

Autologous bone marrow-derived CD133+ stem cell therapy has been used in some clinical trials for patients with chronic total occlusion and ischemia, myocardial infarction, hepatic fibrosis, and liver regeneration as well as bone regeneration showing an excellent safety profile. All these findings support the use of this subtype of stem cells to treat endometrial pathologies such as AS and EA and also highlight the potential use of stem cells to treat these incurable pathological conditions.

CD133 + Bone Marrow Derived Stem Cells

Human CD133 is a transmembrane glycoprotein of 865 amino acids with a total molecular weight of 120 kDa. This protein consists of an N-terminal extracellular domain, five transmembrane domains with two large extracellular loops, and a 59 amino acids cytoplasmic tail (51). CD133 is found in many cell lines and most adult tissues with the exception of mature peripheral blood leukocytes, although it is widely known that the expression of this biomarker is more restricted to undifferentiated cells that include endothelial progenitor cells, hematopoietic stem cells, fetal brain stem cells, kidney stem cells, prostatic epithelial stem cells and liver stem cells (Handgretinger et al., 2003).

CD133 expression is regulated by several extracellular or intracellular factors and usually correlates with changes of cell type and function. In this sense, conditions such as hypoxia, mitochondrial dysfunction or depletion of mitochondrial DNA induce a reversible up-regulation of CD133 expression. The number of CD133+ cells remain relatively constant within the bone marrow, blood and different tissues. However, when cells or tissues are damaged by chemical, physical or mutational causes, CD133+ progenitor or stem cells are activated to self-renew, proliferate and differentiate in order to repair this damage.

Cells derived from bone marrow coexpressing CD133+ and vascular endothelial growth factor receptor 2 (VEGFR2) represent a subpopulation of cells known as endothelial progenitor cells (EPCs) with endothelial progenitor capacity (Handgretinger et al., 2003) that can be mobilized to the circulation and can improve neoangiogenesis of preexisting endothelium.

CD133+ BMDSCs have been previously used in clinical trials for regenerative medicine in nonhematological applications (Rafi and Lyden, 2003) and have functionally contributed to neoangiogenesis during wound healing and limb ischemia, postmyocardial infarction, endothelialisation of vascular grafts, atherosclerosis, retinal and lymphoid organ neovascularization and tumor growth. For instance, cells isolated from the peripheral blood using CD133 antibodies have been able to enhance angiogenesis, astrogliosis, axon growth and functional recovery in a mouse spinal cord injury model. In another study, embedded CD133+ cells in atelocollagen gel within a silicone tube used to bridge a 15 mm defect in the sciatic nerve of athymic rats, regenerate within 8 weeks the nerves and the transplanted CD133+ cells differentiated into Schwann cells. Moreover, G-CSF-mobilized peripheral blood CD133+ cells enhanced histologically and functionally recovery from skeletal muscle injury in a rat model contributing to the environment for muscular regeneration.

Mechanisms of Action (MoA)

The EMEA has recently categorized CD133+ cells as an Advanced Therapy Medicinal Product (ATMP) with certain regenerative properties such as tissue remodeling, tissue regeneration and neoangiogenesis.

These effects are exerted through different MoA: Paracrine activity, endometrial stem cell differentiation/cell fusion, endometrial resident stem cell recruitment/activation and endothelial differentiation. Paracrine activity and endometrial resident stem cell recruitment/activation cause and immediate short-term effect and seem to work at larger scale compared to endometrial and endothelial differentiation that has a more stable long-term effect, but seem to be more residual MoA. Interestingly the paracrine effects can contribute to endothelial regeneration as well as endometrial resident stem cell recruitment/activation as shown in Fig. 1.

Fig. 1 Different MoA of CD133+ cells and interaction among them. The effect of CD133+ cells consists in tissue regeneration, tissue remodeling and neoangiogenesis. Some mechanisms act at short term whereas others have long term effects.

Preclinical Studies of CD133+ BMDSC in AS

Several AS model in rodents has been reported mostly based on physical damage of the endometrium and some preclinical studies have assessed the effect of stem cell therapy in these pathological conditions. In a recent study animals where AS was mechanically induced were divided into two groups (Cervello et al., 2015): In Group A, both uterine horns of the mice were damaged and human cells previously labeled with super paramagnetic iron oxide (SPIOs molecules) were injected intrauterine into only horn only whereas in Group B, only the left horn was damaged and human cells were administered by tail vein injection. Subsequently, uteri were excised after 90 (Group A) or 12 days (Group B) and subjected to Prussian blue, Ki67 and trichrome staining, as well as analyzed for paracrine gene expression. The cells used in this study where an aliquot of the cells extracted from the patients enrolled in the pilot study (Santamaria et al., 2016). Cell engraftment and localization were analyzed by Prussian blue staining, endometrial proliferation by Ki67 staining and quantitative reverse transcriptase–polymerase chain reaction (qRT-PCR) of marker genes.

Prussian blue staining was used to detect accumulation of iron deposits of the SPIO-labeled cells. Human labeled cells seemed to be mostly engrafted around small endometrial vessels in all damaged uterine horns regardless of the route of cell administration or timing. Quantification of iron-positive cells revealed that 0.59% and 0.65% of engrafted cells were present after intrauterine or tail vein injection, respectively. However, no cells were detected in spleen, liver and kidney. Therefore, we observed that, systemically or locally injected, CD133+ cells have the ability to home to and engraft selectively in the damaged endometrium.

Moreover, the epithelial glands of the CD133+ cells treated horns showed a statistically significant increase of Ki67+ cells in comparison with nontreated horns, regardless of the administration route. After intrauterine injection, the proliferation rate increased from $14\% \pm 10.37\%$ to $23.15\% \pm 10.89\%$ ($P < 0.01$) at 90 days after administration, whereas, after tail vein injection, Ki67+ cells increased from $6.92\% \pm 7.03\%$ to $20.55\% \pm 10.89\%$ ($P < 0.05$) 12 days after administration. The expression of several well-described paracrine molecules such as bone morphogenetic protein 6 (Bmp6), platelet-derived growth factor β (Pdgf β), thrombospondin 1 (Thbs1), Tumor necrosis factor α (TNF- α) and Insulin-like growth factor 1 (IGF-1) was compared by qRT-PCR. Statistical differences were seen in the up-regulation of Thbs1 (2.065 vs. 0.752 fold-change; $P < 0.05$), and the downregulation of IGF-1 (0.651 vs. 0.995 fold-change; $P < 0.05$) in the treated damaged horns in comparison with nontreated damaged horns in the intrauterine administration group (Group A).

These results suggest that human CD133 BMDSCs induced indirect proliferation of the neighboring endometrial cells in the damaged endometrium mainly at the epithelial compartment. However, the endometrial cell proliferation observed appears more related to the secretion of soluble factors acting by a paracrine fashion than a direct proliferation of the transplanted cells.

Other groups have also shown similar effects and stem cell engraftment and improvement in reproductive outcome in a rodent model of AS using total Bone Marrow Stem Cells (Alawadhi et al., 2014). Finally, an other group did not observe stem cell engraftment and highlighted the paracrine effect of these stem cell therapy whereas other groups have observed engraftment and full differentiation of these stem cells into stromal and epithelial cells (Ikoma et al., 2009; Taylor, 2004).

Clinical Studies of CD133+ BMDSC in AS and EA

Recently a prospective, experimental, noncontrolled, open labeled study in 18 patients aged 30–45 years with refractory AS or EA was reported (Santamaria et al., 2016). A total of 16 of these completed the study and the end point consisted in assessing the use of CD133+ BMDSC as a potential therapy to refractory cases of AS and EA. Prior to the enrolment, 8 out of 11 patients diagnosed with AS and all the patients diagnosed of EA had previously undergone a mean of 2 (range 1–9) hysteroscopy and 2 subsequent cycles of HRT after each hysteroscopy with no clinical neither sonographic improvements.

In this study an initial ecographical and hysteroscopic diagnosis was performed in proliferative phase. Uterine cavities were assessed following the American Fertility Society (AFS) Classification and adhesions were removed in AS with sharp and blunt scissors. All patients received Hormonal Replacement Therapy (HRT) immediately after the surgery for 2 months.

Then BMDSCs were mobilized into peripheral blood after administration of recombinant human granulocyte colony stimulating factor (G-CSF) at a dose of 10 $\mu\text{g/kg/day}$ for 5 days. G-CSF is a cytokine extensively used for this purpose in both autologous and allogeneic donors (59). One day after the last injection, isolation of the Peripheral Blood Mononuclear Cells by apheresis through peripheral venous access and then, CD133+ cells were isolated. A mean of 124.39 million cells (range 42–236) were obtained. These cells delivered into the spiral arterioles by catheterisation. As shown in Fig. 2, spiral arterioles lay next to the endometrial stem cell niche. Therefore, this delivery method represents an effective minimally invasive approach to homogeneously instill these cells next to the endometrial niche and seems to have an increased engraftment as Liu et al. has recently shown in rodent models.

Three months after the stem cell instillation, the endometrial cavity was re-scored with a second-look hysteroscopy and in some patients a third look hysteroscopy was performed 5–6 months after stem cell instillation. All the patients experienced an improvement in the scores and stages although their cavity was not completely normalized in all the cases. Specifically, all patients diagnosed with stage III AS improved to stage I, while one of the two patients affected with stage II showed a completely normalized endometrial cavity and the other improved to stage I. The remaining patients initially with stage I improved in qualifying score.

Clinically, all the treated patients showed a significant improvement in terms of duration and intensity of the menstrual period specially in the first 3 months after stem cell instillation (Fig. 3). However, this effect seemed to decrease progressively from a mean

Fig. 2 Image of uterine artery catheterization. Spiral arteries that vascularize the basal layer of the endometrium are clearly visible when instillation is performed in the distal part of the uterine artery.

Fig. 3 Volume of the menstrual period before and after CD133-BMDSC treatment. All the patients required a larger number of pads/day right after the treatment, but the effect seemed to decrease with time.

of 5.06 days (ranging from 3 to 7) in the first month to 3.25 days (ranging from 1 to 3) in the third month after cell therapy. Menstrual volume assessed by number of pads/day used also decreased from a mean of 2.69 (ranging from 1 to 5) to 1.75 (ranging from 1 to 4).

Moreover, a statistically significant improvement in endometrial thickness was observed in AS patients from 4.3 mm (range from 2.7 to 5.0 mm) to 6.7 mm (range 3.1–12 mm; $P = 0.004$) whereas in the EA group improved from 4.2 mm (range 2.7 to 5.0 mm) to 5.7 mm (range 5–12 mm; $P = 0.03$) (Fig. 4).

CD133+ BMDSC correspond to circulating endothelial progenitors (CEPCs) with the capacity to improve neoangiogenesis. AS a matter of fact, a statistical significant increase in number of blood vessels in the endometrium was observed 3 months after stem cell instillation together with a histological improvement of the stromal and epithelial layers of the endometrium was clearly visible. However, this process seemed to decrease 6 months after the cellular therapy as observed with the duration and intensity of menses. Interestingly, no side effects related to treatment were observed during the study.

Fig. 4 Endometrial thickness measured in proliferative phase before and after stem cell therapy. In this study each patient acts as her own control. There is a statistical significant increase in the endometrial thickness after stem treatment compared to the measurements before CD133 + BMDSCs instillation.

This study was designed as a pilot study where each patient represented its own control after failed surgical and assisted reproductive treatments. The functionality of the treated endometrium was assessed through the reproductive outcome of patients who underwent ART after stem cell therapy. Briefly, three patients became pregnant spontaneously, 2, 4 and 19 months after cell therapy, resulting in two healthy babies born and a miscarriage at the 17th week due to a premature rupture of membranes, 2 weeks after a Corial Villous Sampling. Seven positive pregnancies were obtained after 14 embryo transfers, resulting in three biochemical pregnancies, one miscarriage at the 9th week due to a chromosomally abnormal embryo identified after the analysis of the products of conception, one ectopic pregnancy, and three healthy new born out of two patients since one was a twin pregnancy. In one patients, embryo transfer was canceled due to chromosomal abnormalities in all of the embryos and, in another case, transfer was not performed due to failure of cell therapy.

Other studies have also suggested (Nagori et al., 2011; Singh et al., 2014) positive results in treating AS with stem cell therapies with the aim to regenerate the endometrium. In the first reported case (Nagori et al., 2011), CD9, CD40 and CD90 autologous bone marrow stem cells were placed into the endometrial cavity to treat AS in a patient undergoing egg donation with success while another series of six cases described the direct placement of noncharacterized mononuclear stem cells into the sub-endometrial zone with a needle. In this latter study a statistically significant restoration of the endometrial thickness (ET) was reported compared to baseline measures ($P < 0.05$) with menstruation reported in 5/6 women (Singh et al., 2014). MNCs were isolated by a Ficoll density separation method and a volume of 3 mL of MNC were implanted in the subendometrial zone transmyometrial at 2–3 sites (fundus, anterior and posterior part) of the myometrium. However, no reproductive outcomes were assessed in this study.

Future Perspectives

On the whole, all these findings suggest regenerative medicine may play an important future role in the treatment of incurable infertility in endometrial pathologies such as AS and EA. It seems quite obvious that further studies are mandatory in order to better important issues such as dosage, MoA and refining the protocol. In this sense, the EMA has recently issued a positive opinion to label CD133 + cells as the first orphan drug designed (ODD) for the treatment of AS and phase I/II and phase III trials are planned in the near future.

Other important advances such as bioengineering, nanotechnology or development of biomaterials together with stem cell therapy may help in the future to optimize and improve the efficiency of these regenerative therapies.

The Origin of Gene Editing Technology

DNA damage can occur in several situations: after exposure to ionizing radiation or chemotherapy, during DNA replication, or following experimental manipulation through the action of endonucleases. DNA double strand breaks (DSBs) are often injurious to the cell, causing genome instability and mutations. Luckily, the DNA repair machinery helps to repair this damage, thereby preventing the formation of DNA mutations that can cause disease. The ability of DNA damage to elicit DNA responses forms the basis of the gene-editing concept. There are two main repair pathways for DSBs: (1) nonhomologous end joining (NHEJ), and (2) homologous recombination (HR) (Fig. 1) (Ceccaldi et al. 2016).

The NHEJ pathways are active throughout the cell cycle and are the most common mechanism for DSB repair. However, these pathways are prone to errors and often result in genetic insertions or deletions, called indels. HR is initiated only in the S or G2 phases of the cell cycle, when a sister chromatid is available to provide a homologous donor template for the repair process. This process is referred to as homology-directed repair (HDR) in the context of an exogenous DNA repair template. This property of HR was used in the early 1980s to insert and to repair genes in mammalian cells by HDR. Later, these techniques were applied to mouse embryos to generate transgenic mice, and the era of genetic engineering was born. These important early studies were performed by Drs. Oliver Smithies, Mario Capecchi, and Martin Evans, who together pioneered HR-mediated gene editing in mouse embryos. They would later share the 2007 Nobel Prize in Physiology or Medicine “for their discoveries of principles for introducing specific gene modifications in mice by the use of embryonic stem cells”.

In the 1990s, gene targeting in mammalian cells using HR was further improved by Dr. Maria Jasin and colleagues when they used the yeast homing endonuclease I-SceI (Rouet et al., 1994). This enzyme generates site-specific breaks in chromatin engineered to contain the 18-bp rare restriction site for this enzyme. Importantly, this site is not found in the mouse or human genomes, so the I-SceI cleavage is highly specific. Cutting with this enzyme enhanced HR up to 500-fold at the target locus, foreshadowing the use of designer site-specific endonucleases to enhance gene editing. These next-generation endonucleases include the zinc finger nucleases (ZFNs) and the transcription activator-like effector nucleases (TALENs), which combined the DNA-binding specificity of zinc fingers or TALE transcription factors from plants, with the DNA cutting activity of the FokI endonuclease (Miller et al., 2011; Kim et al., 1996) (Fig. 1).

One of the major breakthroughs achieved in the field of gene editing occurred in the late 1980s, when a group of researchers discovered a strange topology at the 3' end of the alkaline phosphatase gene in *Escherichia coli*. This consisted of 32 nucleotide sequences, flanked by short invariable palindromic repeats—the first known description of a clustered regularly interspaced short palindromic repeats (CRISPR) array. In 2005, several laboratories demonstrated that the unique spacer regions found in CRISPR

Fig. 1 Gene editing technologies to repair DNA DSBs (ZNFs, TALENs, and CRISPR/Cas9).

arrays actually mapped to phage genomes, hinting that CRISPR may serve as an adaptive immune response to phage infection through an RNA-guided process (Bolotin et al., 2005; Mojica et al., 2005; Pourcel et al., 2005). The molecular mechanism of this immune response involves the transcription of CRISPR arrays into RNA, which is then cleaved and loaded into CRISPR-associated (Cas) proteins (Cas9). This RNA:protein complex then mediates RNA-guided dsDNA endonuclease activity. Furthermore, it was discovered cas9 can be reprogrammed to target novel sequences with an in vitro transcribed single guide RNA (sgRNA) (Fig. 1).

For many years, researchers had been searching for a tool for easily inducing mutations in a targeted fashion. While some progress had been made using engineered meganucleases, ZFNs, and TALENs, these systems had numerous limitations. They were either expensive, labor-intensive, or both, as the targeting mechanisms were based on protein-nucleic acid interactions, thereby requiring a custom-designed protein for each genetic locus of interest. The promise of RNA-guided nuclease activity afforded by CRISPR-based approaches led numerous groups to recognize immediately that this technology could potentially be used to induce targeted, DSBs in eukaryotes, which previously could only be accomplished with much difficulty. DSBs produced either by previously available technologies or CRISPR-based systems, are repaired by low-fidelity DNA repair pathways, leading to the production of indels—a class of mutations characterized by the random insertion or deletion of nucleotides at the site of the DSB.

The Differences Between Gene Editing Tools

As mentioned previously, there are four basic nuclease technologies: meganucleases, ZFNs, TALENs, and CRISPR/Cas9 nucleases. Differences are described in detail below (Porteus, 2015).

Engineered meganucleases are derived from a large family of natural homing endonucleases. A small number of these endonucleases have been designed to recognize natural target sites in the genome via a variety of strategies, including structure-based design and yeast surface display. Natural meganucleases have historically been the gold standard for specificity, but the challenge of engineering meganucleases for novel target sites has limited their translational development. Furthermore, the specificity of engineered meganucleases has not been fully evaluated.

Zinc-finger nucleases (ZFNs) are artificial proteins in which a zinc-finger DNA-binding domain is fused to the nonspecific nuclease domain from the enzyme *FokI*. To cut DNA efficiently, the nuclease domain must dimerize, a pair of ZFNs must be engineered for each target site, and these must be oriented correctly to allow dimerization. Zinc-finger-DNA binding domains can be engineered for novel target sites using a variety of strategies, including phage display, modular assembly, bacteria-based two-hybrid and one-hybrid systems, and combination approaches. Although ZFN design strategies are continuously being improved, engineering ZFNs that have high activity and high specificity to endogenous target sites remains a challenge. The best-quality ZFNs created using a combination of phage display and modular display have entered into clinical trials in which, for example, engineered T cells have been shown to be safe.

TAL effector nucleases (TALENs) are also artificial proteins. They share a similar structure to ZFNs in which an engineered DNA-binding domain is fused to the nuclease domain of the enzyme *FokI*. In TALENs, the DNA-binding domain is engineered by assembling a series of TAL repeats, with each repeat mediating the interaction with a single base through a two amino acid repeat variable di-residue (RVD) that can be described by a simple code. Thus, creating a highly active TALEN is much simpler than creating a highly active ZFN and simply involves using the code to assemble the correct TAL repeats needed to recognize a novel target sequence. In addition to the TAL repeats that use natural RVDs, TAL repeats that use engineered RVDs are now being used to create TALENs. These engineered RVDs may have increased specificity over natural RVDs, although this point remains to be further studied. As with ZFNs, a pair of TALENs must be engineered to recognize each target site of interest. Even TALENs that use TAL repeats containing natural RVDs may have better specificity than ZFNs.

CRISPR/Cas9 nucleases (CRISPR is an abbreviation of “Clustered Regularly Interspaced Short Palindromic Repeats”) are derived from a bacteria-based adaptive immune system. In contrast to the other three technologies, the CRISPR/Cas9 nuclease system does not derive specificity through protein–DNA interaction, but instead through RNA–DNA Watson–Crick base pairing. In the CRISPR/Cas9 system, a single-guide RNA (sgRNA) is designed such that the 20-bp recognition region of the sgRNA is identical to the desired target site. The target site must be nearby to a proto-spacer adjacent motif (PAM) sequence, which the Cas9 protein uses to identify target sites. The multifunctional Cas9 protein, in complex with the sgRNA, is able to unwind double-stranded DNA, to interrogate whether the guide strand is sufficiently identical to the target site, and to then create a rounded DSB if there is sufficient identity. Thus, CRISPR/Cas9 nucleases can be engineered very easily, and many of the designed nucleases (between one third and one half) are active at the desired target site.

The Potential Therapeutic Relevance of Genome Editing Technologies

Gene editing technologies are powerful tools for basic research, but the ultimate goal is to translate these systems into therapeutic applications. The potential use of gene editing in the clinic emerged from the idea that the best way to treat monogenic diseases would be to develop a method for correcting the disease-associated mutation, but that it would also be necessary to make more dramatic changes to the genome to cure diseases with multifactorial origins, which are more common. The use of genome editing

to cure monogenic disease is conceptually simple, but the true power of genome editing tools is that they provide a mechanism for making more sophisticated genomic changes, which can be used to cure more common diseases or to modify their course. In fact, there are currently several companies developing gene editing-based approaches to treat disease, including Editas Company, Intellia Therapeutics, CRISPR Therapeutics, OvaScience, and Sangamo Therapeutics.

Prospective Therapeutic Applications of NHEJ- and HR-Mediated Genome Editing

The use of ZFNs for therapeutic purposes has primarily been focused on common inherited monogenic disorders, such as severe combined immunodeficiency (SCID) and cystic fibrosis (CF), as well as acquired infections, such as human immunodeficiency virus (HIV) and hepatitis B virus (HBV). Studies have been conducted in a variety of human and animal cell lines to test systems for NHEJ-mediated gene disruption, and HDR-based gene correction (through the use of donor templates). ZFNs are among the most mature gene editing technologies, with the successful completion of early phase human clinical trials to treat HIV. A number of ZFN-based therapeutic applications have been investigated, including those to treat sickle cell anemia, hemophilia B, Duchenne muscular dystrophy (DMD), paroxysmal nocturnal hemoglobinuria (PNH), X-linked chronic granulomatous disease (XCGD), ataxia, retinitis pigmentosa (NARP), Leigh's syndrome, Down syndrome, Parkinson's disease, and HBV.

Similar to ZFNs, the therapeutic potential of TALENs has been demonstrated in cellular and animal models for a variety of genetic and acquired disorders. Examples of both gene disruptions and gene corrections by NHEJ and HDR, respectively, have been reported. While TALEN technologies are not as mature as those utilizing ZFNs, and no clinical trials have been initiated, a number of studies are currently underway. Including efforts to treat sickle cell anemia, DMD, alpha1-antitrypsin deficiency (A1ATD), polycythemia vera (PV), recessive dystrophic epidermolysis bullosa (RDEB), SCID, mitochondrial disease, malaria, HIV-1 resistance, HBV replication, HPV infections, and various cancers.

Even though use of the *CRISPR/Cas9* system as a gene editing technique was first reported in January 2013, significant progress has been made in the last 2 years to demonstrate therapeutic potential for several diseases, including sickle cell anemia, DMD, CF, A1ATD, PV, cataracts, Barth's syndrome, hereditary tyrosinemia type I (HTI), HIV-1 resistance/infection/immunization, HBV, Epstein-Bar virus (EBV), HPV/cervical cancer, osteosarcoma, and cardiovascular disease. This is likely because the simplicity and relative affordability of the system makes it accessible to a wide array of researchers. Looking at disease targeted for CRISPR/Cas9-, ZFN-, and TALEN-based approaches, there is a clear effort to evaluate the utility of these three gene editing technologies for treating inherited monogenic disorders, and for antiviral therapy. For the CRISPR/Cas9 system, the first clinical trials may still be years away, but recent in vivo studies, including some performed in non-human primate embryos, demonstrate rapid progression toward that goal.

Potential Applications of Gene Editing Technology in Reproductive Biology

There are several potential applications for the CRISPR/Cas9 technology in reproductive biology, including those that target pluripotent stem cells, gametes, or embryos (Vassena et al., 2016). The first theoretical option for preventing a genetic disorder in the progeny is to use gene editing to correct the mutation in pluripotent stem cells (induced pluripotent stem cells (iPSCs) or somatic cell nuclear transfer-human embryonic stem cells (SCNT-hESC)) that have been obtained from a patient with a specific disease. These type of cells are ideal for researching technologies for gene editing because can be grown easily. Following gene correction, these pluripotent stem cells must be differentiated in vitro toward oocytes or sperm for use in assisted reproductive technology (ART). The possibility of creating in vitro stem cell-derived gametes in mice was recently demonstrated by two revolutionary papers by Hayashi et al., and current research is being conducted to achieve this result in humans to overcome certain types of infertility (Vassena et al., 2015).

For female gametes, it has been demonstrated in mice that TALEN and CRISPR/Cas9 tools can be used to eliminate mtDNA molecules in oocytes or zygotes (Reddy et al., 2015; Wang et al., 2015). For males, it is currently very difficult to generate post-meiotic sperm from spermatogonial stem cells (SSCs) in vitro. Thus, it appears that SSCs are the better target for treating male infertility (specifically, the inability to generate mature sperm). Recent studies in mouse SSCs have nudged the field closer toward using gene editing to treat male infertility.

Finally, the efficiency of genomic editing is extremely low in embryos. This results from inefficient nuclease cutting and/or inaccurate DNA repair before the embryo undergoes cleavage. Although this is a major problem in generating mosaic embryos, several studies in different animal models have demonstrated the feasibility of gene editing in animals. In nonhuman primates, microinjection of CRISPR/Cas9 or TALENs into zygotes has led to the birth of modified offspring with genome-modification efficiencies that range from 0.5%–40.9% per injected zygotes. Very recently, CRISPR/Cas9 editing was performed in human zygotes to verify its specificity and fidelity. Also, a novel technique, called genome-editing via oviductal nucleic acids delivery (GONAD) has been effectively delivered to preimplantation embryos within the intact mouse oviduct using a simple electroporation method, resulting in the desired genetic modification in the embryo. Unfortunately, these edited embryos were mosaic (this has been seen in other model systems as well) and a substantial number of “off-target” mutations were identified (presumably from nonspecific activity of the CRISPR/Cas9 complex, intrinsic abnormalities of the embryos originating from the 3 pronuclei (3PN) zygotes, or a combination of both).

Recently, it has been published up to now a major milestone in the field of gene editing. Mitalipov's team addressed several steps to improve the precision and safety of the CRISPR/Cas9 technique. As we mentioned above, to date, the CRISPR/Cas9

technology used in embryos and pluripotent stem cells has frequently generated mosaics by repairing the mutation in some cells but also by introducing a high rate of unwanted off-target mutations or extra mutations in the targeted gene (nonhomologous repair). However, Mitalipov's team considerably improved on previous efforts by injecting the CRISPR/Cas9 components together with the patient sperm directly into normal MII oocytes. Until now, the Cas9 complex has been injected directly into the zygote. Remarkably, they now found high efficiency of homologous-repair, no evidence of off-target genetic changes, and only a single mosaic generated in an experiment involving 58 human embryos (Ma et al., 2017).

Obviously, more research in animal models is needed to improve the safety and efficiency of this method for germline correction through genome editing.

Gene Editing to Treat Germline Genetic Disorders: The Case of Mitochondrial Diseases

Mitochondrial diseases are among the most devastating inheritable diseases, with the most severe forms causing death shortly after birth. While there is currently no cure for mitochondrial diseases, advances in science have provided ways to prevent disease transmission. One mitochondrial-disease prevention method is preimplantation genetic diagnosis (PGD), a technique in which cells taken from in vitro fertilized (IVF) embryos prior to uterine implantation are screened to select healthy embryos. Specifically, PGD has been shown to significantly increase the probability of producing healthy offspring for heteroplasmic carriers of mitochondrial DNA (mtDNA) mutations. However, PGD is not a valuable test for all patients. While it provides information about the mtDNA, it offers no intervention when the mtDNA is found to be mutant, as is often the case with homoplasmic or heteroplasmic carriers close to the disease threshold. For this reason, the field of mitochondrial disease prevention is limited until technological interventions are ready for clinical use. In recent years, a novel method of mtDNA replacement therapy (MRT) has emerged as a promising approach for preventing mitochondrial disease transmission (Fogleman et al., 2016; Gómez-Tatay et al., 2017). There are currently four primary techniques for mtDNA replacement: (1) metaphase II spindle-chromosome complex (MII-SCC) transfer, (2) pronuclear (PN) transfer, (3) germinal vesicular (GV) transfer, and (4) polar body (PB) transfer (Fig. 2).

For *MII-SCC transfer*, the mature oocyte containing mutant mtDNA is progressed to metaphase II when the chromosomal material is arranged along the metaphase plate. The nucleus is then harvested and implanted into a healthy, enucleated donor oocyte (Fig. 2A). This technique allows for the newly constructed oocyte to be fertilized by a viable sperm after the transfer occurs or by activation of the reconstructed oocyte. However, because of the imprecise nature of the spindle complex, this technique carries the risk of extracting more cytoplasm and increasing the amount of mutated mtDNA that is transferred.

PN transfer is the process by which pronuclei from both the sperm and oocyte (before fusion) are removed from parental zygotes and placed in a donor zygote that was previously fertilized and enucleated (Fig. 2B). The advantage of this technique is that it allows for the extraction of two, well-defined pronuclei after the sperm has been introduced into the oocyte, potentially reducing the amount of cytoplasm that is transferred with the pronuclei and decreasing the carryover of mutated mtDNA. PN transfer, rather than MII-SCC transfer, may be the technique worth pursuing in future studies to achieve better outcomes for patients with high levels of mutant mtDNA. While it is difficult at this point to compare MII-SCC and PN transfer techniques in a meaningful way, both have advantages and show great promise.

GV transfer involves transferring a healthy, immature oocyte nucleus to a healthy donor egg. This is potentially another way to reduce the amount of inviable mtDNA, but more studies are required (Fig. 2C). GV transfer is performed during the arrested prophase of meiosis I, when two copies of each of the 23 pairs of chromosomes are present. Because of the large size of the nucleus at this stage, it is easier to successfully harvest. The reconstructed oocyte is then matured in vitro prior to fertilization, or fertilized with sperm. However, during GV harvest, small amounts of residual ooplasm may be transferred as well, thus it is possible that mutated mtDNA is present in the newly reconstructed oocyte.

The last method is *PB transfer*. The first polar body (PB1) is formed during egg maturation. In this process, the DNA duplicates so that the egg contains four chromosome sets. Of these, two will remain within the egg, while the other two will package, forming the PB1, which is extruded and will not be present in the resulting embryo. The second polar body (PB2) is formed during fertilization. One set of the remaining chromosomes is packaged, forming the PB2, while the other set will form the nuclear DNA of the embryo, together with the sperm DNA. Polar bodies contain very few mitochondria, which is an advantage for avoiding mitochondrial carryover. In PB transfer, the PB1 is transferred to an unfertilized enucleated donor egg (PB1T), or the PB2 is transferred to a half enucleated zygote (PB2T). Thus, the first strategy is strictly preventive, whereas the second is not (Fig. 2D).

Mitochondrial Gene Editing With TALENs

As we mentioned above, it is possible to use TALENs to specifically target mtDNA. These mito-TALENs can be used to cleave mutated mtDNA, and have already been used to selectively eliminate defective mtDNA in both unfertilized mouse eggs and in murine embryos. Moreover, these genetically modified mice gave birth to two successive generations of healthy mice. When mRNA encoding mito-TALENs was injected into an oocyte from a heteroplasmic mouse that carried two mtDNA haplotypes (NZB and BALB), mtDNA heteroplasmy shift was achieved. Furthermore, mito-TALENs successfully targeted and reduced the levels of mutated human mtDNA when injected into human patient cells that had been fused to a mouse oocyte (Reddy et al., 2015).

Fig. 2 mtDNA replacement techniques: (A) MII SSC transfer, (B) pronuclear transfer, (C) germinal vesicle transfer, and (D) first and second polar body transfer.

Mitochondrial Gene Editing With CRISPR/Cas9

We are only just beginning to enumerate the enormous possibilities offered by this new biotechnology tool, both in research and in a multitude of clinical applications, particularly in the field of germline genetic modification (mitochondrial diseases). This is reason enough to be curious about the curative potential of CRISPR/Cas9 technologies for carriers of both heteroplasmic and homoplasmic mtDNA mutations. While gene-editing may not affect all mutant mtDNA, it may modify enough to bring the individual below the disease threshold, conferring therapeutic benefits. Although there is considerable hesitation among the scientific community in using this technique in the germ line, studies using nonviable embryos have already been performed. These studies show that the technique works with low efficiency to generate on-target gene modification, but that off-target

mutations are also generated and the resulting embryos are mosaic, as mentioned before. CRISPR/Cas9 has already been successfully used to produce mitochondrial sequence-specific cleavage, as proof of concept that this technique can target specific mitochondrial genes. In the same study, researchers engineered a new version of the enzyme Cas9, mitoCas9, whose localization is restricted to the mitochondrial matrix. This is an important step, as it reduces the risk of off-target mutations in the embryo and prospective children.

CRISPR/Cas9 editing of embryonic mtDNA may represent a more socially acceptable alternative to “three-parent IVF.” Instead of combining the genetics of three individuals, this technique may enable a couple to conceive without requiring donor genetic material. Another advantage of trying to treat mitochondrial disease before implantation is the small number of cells; it may be easier to ensure a reduced mutation load if the embryo is in the 8- or 16-cell stage, rather than waiting to provide a therapeutic intervention after birth, when there are exponentially more cells.

Conclusions

The development of new technologies based on sequence-specific nucleases has resulted in: (1) greatly improved efficiency in targeting specific genomic loci, (2) greater ease in constructing donor vectors, (3) the possibility of genome editing with oligonucleotides, (4) direct genome editing by the electroporation of embryos, and (5) the possibility of multiplexed genome editing. This technological breakthrough makes the possibility of editing the human germline much more feasible than in the past, particularly for embryos that carry mitochondrial disorders. From our point of view, basic studies must be conducted in animal models to better understand mitochondrial biology before these technologies can successfully be used to edit mtDNA. For example, what are the mechanisms of nucleus/mitochondria communication and how is the transmission of mtDNA to the offspring regulated. In particular, what controls variable transmission of heteroplasmy, and how does this affect symptoms of mitochondrial diseases. Since animal studies have limitations in predicting outcomes in humans, subsequent research in humans will be necessary. Similarly, before CRISPR/Cas9 technology can be translated to the clinic, outstanding problems must be resolved, primarily mosaicism and off-target effects. Nevertheless, once technical issues are resolved, editing of the human germline to prevent the birth of a child with a mitochondrial defect should only be considered when already established methods, which do not entail manipulation of the genome (such as PGD), are not available.

Summary

Overview of Volume 6 of Comparative Reproduction involves the topics and sections of modes of reproduction, behavior, development and anatomy of reproductive organs, sex determination and differentiation, gamete structure, oogenesis and ovulation, maternal reserves, spermatogenesis, fertilization, endocrinology, seasonal reproduction, puberty and metamorphosis, pregnancy and parturition, phylogeny and reproduction, wildlife and lab animals, and reproductive technology.

Overview

Volume 6 is focused on Comparative Reproduction in all species and phylogeny when reproduction has been investigated. The focus is on nonmammalian species due to Volumes 1–5 being focused on mammalian reproduction. The first section of Volume 6 is Modes of Reproduction, which involves chapters on sexual reproduction, asexual/unisexual reproduction in plants and animals. Hermaphroditism, viviparity, and oviparity in vertebrates and invertebrates are presented. Reproductive strategies and tactics are reviewed.

The second section involves Reproductive Behavior in a variety of species, including birds, invertebrates, insects, fish, turtles, and mammals. The sexual behavior reviewed includes mate choice and sexual selection, courtship and mating, communication (e.g., song), migration and navigation, nesting, brooding, and parental behavior.

The Development and Anatomy of Reproduction section is reviewed with a focus on comparative analysis between species such as plants and insects. The mammary glands, placenta, and accessory sex glands are tissues compared between species. The Primordial Germ Cells, Sex Determination and Differentiation section involves a variety of species, including fish, *Drosophila*, vertebrates, amphibians, reptiles, birds, and insects. Primordial germ cell development, sex determination, environmentally induced sex determination, and sex reversal are reviewed in the different species. The Gamete Structure section reviews egg and sperm in vertebrates and invertebrates. The Oogenesis and Ovulation section reviews these developmental processes in fish, reptiles, birds, insects, and echinoderms. Oocyte maturation is compared, and impacts on reproduction are reviewed. The Maternal Reserves section reviews maternal RNA and vitellogenesis and yolk proteins in fish, *Drosophila*, birds, insects, crustaceans, and molluscs. The comparative reproduction of maternal reserves is reviewed.

The Spermatogenesis and Spermiogenesis section reviews the topic on fish, elasmobranchs, birds, insects, crustaceans, and molluscs. A detailed comparison is made for each to identify similarities and differences in male germ cell development. The Fertilization section compares the fertilization, sperm storage, and delayed fertilization in numerous species. The Endocrine Control of Reproduction section reviews the comparative cellular organization of pituitary gland in vertebrates. In addition, the endocrine control of reproduction in fish, birds, amphibians, reptiles, insects, crustaceans, and molluscs is reviewed.

A number of reproductive physiology topics are reviewed in the Seasonal Reproduction section for photoperiodism, in the Puberty and Metamorphosis Related to Reproduction section, and in the section on Pregnancy and Parturition in fish, birds, mammals, insects, reptiles, and amphibians. The Olfaction and Reproduction section reviews pheromones and olfactory imprinting and homing in fish, insects, and mammals.

The Overview of Reproduction by Phylogeny section reviews the topic on sponges, corals, jellyfish, flatworms, roundworms, *Caenorhabditis elegans*, rotifer, molluscs, insects, crustaceans, centipedes, sea stars, sea urchins, tunicates, fish, sharks, rays, sturgeons, bony fish, frogs, alligators, turtles, birds, monotremes, marsupials, mammals, and plants. This section provides an extensive comparative reproduction overview for each.

The Reproduction, Exotics/Zoo Animals/Wildlife section reviews reproduction in a variety of species. The reproduction in penguins, hyena, alligators, crocodiles, elephants, snakes, primates, and deer are presented. In addition, the General Reproduction in Lab Animals section presents common lab models and associated reproduction. This includes *C. elegans*, *Drosophila*, cockroaches, tobacco hornworm, sea urchin, zebrafish, and rodents.

The Genetics and Epigenetics in Life History and Reproduction section reviews several very interesting models. This includes honeybees, fish, oysters, and the genetic selection of reproductive traits in animals. The Energetics/Nutrition in Reproduction section reviews a various species such as fish and birds. Hibernation and lactation are other physiological processes reviewed.

The final section on Reproductive Technologies in nonhuman/nonprimate species examines a variety of technologies. Germ cell transplantation in fish is reviewed. Gamete preservation in a variety of species is reviewed. Reproductive cloning in a number of different species is also presented. Captive breeding in wildlife, mammals, birds, fish, amphibians, and reptiles is reviewed. Sex control and sterilization in species such as fish is presented. In addition, methods of sterilization and contraception in mammals and wildlife are reviewed.

The breadth, quality, and educational impact of Volume 6 of the Encyclopedia of Reproduction is solely due to the chapters' authors who are internationally recognized authorities on the topics and contributed significantly to the scientific advances in

the field. All are active researchers who have made major contributions in the area of Comparative Reproduction. The contributors to this volume are very much appreciated.

Glossary

Apomixis A form of parthenogenesis without meiosis, which is here replaced by cell division. It results in offspring being genetically identical to the mother and to each other, except for few mutations.

Automixis A form of parthenogenesis with a modified meiosis. The result can either be offspring being genetically similar to their mothers or different, depending on the mechanisms restoring the original number of chromosomes.

Chromosome Carrier of genetic information (DNA), visible as thread in the nucleus of a cell with a light microscope during certain cell stages.

Clonal Total genetic identity between parents and their offspring.

Fertilisation The fusion of egg and sperm cell.

Gametes In animals, these are egg and sperm cells that have only a single set of chromosomes and fuse during fertilisation.

Genome All genes or genetic material (DNA) present in an organism.

Genomic imprinting Genes are differently expressed (translated into proteins), depending on from which parent they originate.

Gynogenesis A combination of parthenogenesis with sexual reproduction, where sperm from males of a closely related species is only required to initiate cleavage of the egg but no actual fertilisation takes place.

Hemiclonal A reproductive mode where only the female part of the genome is passed on clonally (without meiosis) to the next generation.

Hermaphrodites Organisms that have both, male and female reproductive organs and can possibly reproduce with themselves.

Hybridogenesis A combination of parthenogenesis with sexual reproduction. The eggs that are produced by the females of one species are fertilized by the sperm of males from another species, resulting in hybrids. This process is also called hemiclonal.

Kleptogenesis An intermediate form between gyno- and hybridogenesis, with the occasional incorporation of genetic material coming from males of other species. The name comes from the fact that females “steal” the genetic material of these males.

Meiosis Special kind of cell division that leads to the reduction of chromosomes and is required prior to fertilisation and sexual reproduction.

Mutation Genetic change in the DNA, which can be beneficial or deleterious.

Parthenogenesis Reproductive mode where eggs develop into daughters without any male contribution.

Polyploidy Organisms with more than two sets of chromosomes. They often originate through hybridisation.

Sex in Animals is One Big Genetic Lottery!

The majority of all higher organisms reproduces sexually. In animals, sexual reproduction usually takes place with two parents (females and males) although there are also hermaphrodites which can sometimes reproduce through self-fertilisation. Myriads of other forms of sexual reproduction are known from plants, fungi and unicellular organisms – and such “weird sex” in all its aspects has been the topic of a special issue ([Aanen et al., 2016](#)) to which interested readers should refer.

In animals, sexual reproduction involves the fusion of two gametes consisting of a maternal egg cell and a paternal sperm cell. If these two cells fuse, the egg is fertilized, after which cleavage of the egg and embryonic development starts. Before fertilisation can take place, however, both gamete cells have to undergo special processes, including a special type of cell division called meiosis. While all normal cells in a eukaryotic body contain two (or multiple, see below) copies of each chromosome, egg and sperm cells mostly contain only a single set (called haploid nuclei), as otherwise the number of chromosomes would double with fertilisation in every generation. Humans, for example, have 23 pairs of chromosomes, fruit flies have only four. During meiosis, novel genetic

Fig. 1 The most important steps of meiosis. Different chromosomes are indicated by different size, different genes on each chromosome by different colours. In the second step, crossing over between the two chromatids of the same chromosome occur. The four gametes that are the product of meiosis from parent 1 are all genetically different. Redrawn from Martens, K. (Ed.), (1998). *Sex and Parthenogenesis, Evolutionary Ecology of Reproductive Modes in Non-Marine Ostracods*. Leiden: Backhuys Publishers.

combinations in the gametes are formed because chance decides how the (single) chromosomes are distributed over the four gametes that are the result of meiosis. Furthermore, different parts of homologue chromosomes can be exchanged during meiosis, for example, by crossing over, a process that is called recombination and provides additional means to generate novel genetic combinations (Fig. 1).

Subsequently to meiosis, also fertilisation itself generates novel genetic combinations. This is so, because the gametes of the two parents fuse, which can be genetically very different from each other. But also within each parent, not all gametes have the same genetic constitution so which sperm cell will fertilise which egg cell is to a large part determined by chance. As a result, sexual reproduction leads to offspring that differ genetically from each other and from their parents. Sexual reproduction thus causes a large amount of novel genetic variability each generation within populations and can be regarded as a kind of genetic lottery for the evolutionary success of subsequent generations.

In evolutionary terms, sexual reproduction is a costly process, not only because of the specialized mechanisms like meiosis that are involved, but also because of a variety of other reasons.

Firstly, there is the cost of mating as such. Mating is dangerous because when the two parents actively seek each other, they are exposed to predators, unfavourable environmental conditions etc. Sexual reproduction furthermore often includes complicated and costly courtship and mating behaviours, involving elaborate ornaments, mostly in males. Additionally, during mating, harmful parasites, bacteria, viruses etc. can be exchanged which can infect the other parent and transmit diseases.

Secondly, the two-fold cost of sex holds that fully asexual populations have an advantage as all (female) individuals directly produce offspring, while in sexual populations only half of the individuals (females) do so, males do not. Assuming equal numbers of females and males in a population, asexually reproducing populations will grow twice as fast (Maynard Smith, 1978). Additionally, asexuals should be better and faster colonizers because a single egg is sufficient to found a new population.

Despite its evolutionary cost, sex is still the most common reproductive mode in the animal kingdom and most animal species have sex during at least part of their life cycle. This represents an evolutionary paradox and more than 25 hypotheses have been put forward trying to solve this paradox, which remains to date “the queen of problems in evolutionary biology” (Bell, 1982; Schön and Martens, 2014). But several alternatives to sexual reproduction exist.

Unisexual Reproduction in Animals – Half Clones, Sperm Parasites and Sperm Thieves

In vertebrates, asexual reproduction with female-only populations is historically called unisexuality and does not involve fertilisation of the egg by sperm from males of the same species. About 100 unisexual vertebrate species are known (Avisé,

2008, 2015), and certain lizards, snakes and allies can reproduce fully asexually as described in the next paragraph. However, in contrast to ‘real’ asexual reproduction (see below), eggs in most unisexually reproducing animals cannot develop into viable offspring on their own. One could thus regard these types of unisexual reproduction as kinds of intermediate reproductive modes between sex and parthenogenesis. They probably evolved as a result of hybridisation between different species (see below). Hybridogenesis, one mode of unisexual reproduction, combines parthenogenesis with sexual reproduction. Females produce haploid eggs (with only one set of chromosomes), that are fertilized by males from another, usually closely related, species. Since only the female part of the genome is passed on to the next generation during meiotic egg division (the male chromosomes are discarded during the process), this process is also called hemiclinal (=half clonal and half sexual), and thus differs from fully sexual reproduction. This kind of reproduction occurs in various fish, salamanders and frogs (Avisé, 2008, 2015; see also chapters 15 & 16 in Schön *et al.* (2009)).

In another form of unisexuality, gynogenesis, the sperm of males from closely related species is still required to initiate egg cleavage but not for fertilisation. The male DNA is thus no longer incorporated into the egg, in contrast to what happens in hybridogenesis. Gynogenesis has also been called sperm parasitism, as it is detrimental to the males of the other species that waste their sperm. It is known from many vertebrates and is especially common in fish (see an overview in chapter 15 in Schön *et al.* (2009)) and certain salamanders (Avisé, 2015). In total, less than 0.1% of all vertebrates, excluding birds and mammals, reproduce unisexually. In bird and mammals, genomic imprinting appears to be the main reason why parthenogenesis is absent (see chapters 15 & 19 in Schön *et al.* (2009)).

Finally, there is also an intermediate form between hybrido- and gynogenesis, where occasionally, parts of the male genome “leak” into the offspring. The mechanisms and potential selective advantages of this phenomena, for which Avisé (2015) coined the very fitting name “kleptogenesis” or sperm thieves, are still not well understood.

Asexual Reproduction in Animals – Female Power!

There are at present different concepts of asexuality. One school holds that all reproduction by eggs should be considered sexual and only vegetative reproduction, where animals like flatworms that are cut into two, can survive and develop into two novel individuals, are truly asexual. A second approach defines asexuality as reproduction that might involve the production of gametes but without full meiosis and without fertilisation. We follow this second definition. Following this definition, asexuality in animals involves egg cells that can develop into (asexual) offspring without fusion with a sperm cell, a process also called parthenogenesis. Thus, truly asexual populations consist of females only.

There are many different kinds of asexual reproduction (Bell, 1982; Schön *et al.*, 2009). Some processes still include part of meiosis (“automixis”) while others have only mitotic cell divisions without reductions in chromosome numbers (“apomixis”- diploid cells remain diploid) and which generally result in genetically identical offspring or clones (Loxdale and Lushai (2003); chapter 9 in Schön *et al.* (2009)).

Because of the evolutionary cost of sex explained above, asexuality could be more advantageous than sex and many animals, especially invertebrates and certain unisexuals (see previous paragraphs), are able to reproduce asexually (Bell, 1982; Simon *et al.*, 2003; Schön *et al.*, 2009; Avisé, 2015), and do so for at least part of their life cycle. Asexual reproduction is thus not uncommon in animals (Simon *et al.*, 2003; Schön *et al.*, 2009), but it has a “twiggy” phylogenetic distribution (Bell, 1982). This has long been regarded as evidence for the fact that asexuals are by necessity short-lived and are, evolutionary speaking, dead ends of the tree of life. This view has meanwhile been challenged and closer inspection has revealed that there appears to be an even distribution of the age of asexuals (Neiman *et al.*, 2009) without a distinct gap between young and very old asexual taxa. Still, animal groups that have been asexual for millions of years (the so-called ancient asexuals) are very rare, and only four potential cases exist (see chapters 11–13 in Schön *et al.* (2009), Schwander *et al.* (2011)). These lineages are the ideal model organisms to study the evolutionary consequences of asexuality as we would expect that they have developed special mechanisms to overcome the disadvantages of the loss of meiosis and recombination, and its resulting loss of genetic diversity in populations.

The Origin and Maintenance of Unisexual and Asexual Reproduction

Genetic Factors

It is assumed that sexual reproduction was the ancestral condition in early animals. This means that all forms of asexuality and unisexuality described above have developed from sexual ancestors, and this can have been caused by both intrinsic and extrinsic factors or combinations thereof.

The evolution of parthenogenesis is a two-step process: firstly, meiosis needs to be suppressed, and secondly, eggs must be able to initiate cleavage and develop further without the trigger of fertilization. The loss of meiosis can be a relatively simple and spontaneous process, involving only few genetic changes. In animal genomes, no parthenogenetic genes *sensu stricto* have so far been identified as opposed to in plants, but in certain cladoceran crustaceans (Eads *et al.*, 2008), a small genomic alteration has indeed led to the loss of meiosis. With the increasing availability of genomic data from asexual animals, it is likely that more such examples will become known in the near future.

The second step, initiating cleavage and further development, is often seen as a gradual process. The following three steps can be recognised. (1) In hybridogenesis, sperm is still required for both egg cleavage and for further development. (2) In gynogenesis, foreign sperm is still required to initiate egg cleavage, but after that eggs can develop without fertilisation. (3) In parthenogenesis, eggs can start cleavage and develop further by themselves without any need for contact with sperm.

Unisexual and asexual reproduction is often a consequence of hybridisation, the mating of females and males from two different species. Such hybrids are often characterized by polyploidy (multiple sets of chromosomes) and can no longer reproduce sexually with normal meiosis (see above). Hybridisation is very common in plants and probably, also in animals, as the application of novel genomic techniques shows (for recent examples, see [Flot et al. \(2013\)](#) on bdelloid rotifers or [Blanc-Mathieu et al. \(2017\)](#) on root knot nematodes). Young (and hybridogenic) hybrids can have high genetic variability through the genetic material that is received from both parental species. This kind of hybrids thus potentially combines the benefits of both reproductive modes ([Bell, 1982](#)). In contrast, gynogenesis continuously omits the male part of the genome during egg division, while no males are present any more in fully parthenogenetic animals, both resulting in a loss of genetic variability in asexuals over time.

There are several other processes (apart from hybridisation) that can lead to asexuality but which also combine, at least to some extent, the advantages of sexual, unisexual and/or asexual reproduction. These include asexuals with very occasional input of male genetic material (kleptogenesis, see “unisexuals” above), and certain kinds of automictic parthenogenesis where parts of the meiotic processes and recombination still take place (see above “asexuality” and [Bell \(1982\)](#); chapter 1 in [Martens \(1998\)](#); chapter 4 in [Schön et al. \(2009\)](#)).

Environmental Factors

The reproductive mode can also be influenced by the environment. Decreasing temperatures and crowding conditions in populations are known factors triggering the switch from asexual to sexual reproduction in so-called cyclic parthenogenes. These have their name from the fact that populations go through alternative cycles of asexual and sexual reproduction. Sex is required to survive winter (aphids), or produce resting stages (cladocerans, rotifers; see chapters 14 & 15 in [Schön et al. \(2009\)](#)). Again, cyclic parthenogenesis is a way to combine the evolutionary advantages of both reproductive modes.

Another evolutionary avenue to mixed reproduction in certain species of non-marine ostracods is the existence of three genders, sexual and asexual females plus males ([Martens, 1998](#)). Often, these three genders co-occur ([Martens, 1998](#)). The physical closeness of asexual females and males promotes their mating and consequently, the generation of new asexual lineages through hybridisation, causing polyploid, asexual offspring with novel genetic input from their sexual relatives.

Finally, in many invertebrates, asexuality can also be caused by bacterial infections (see the recent review by [Ma and Schwander \(2017\)](#)), with *Wolbachia* being the best known and studied example ([Werren et al., 2008](#)). These bacteria are found in close contact with their hosts, for example, in the reproductive organs where they can arrest meiosis, kill males or change genetic males into phenotypic females.

The Paradox of Sex – Good and Bad Genes

More than 25 evolutionary hypotheses and combinations thereof have been put forward to explain why sex is so prevalent despite its evolutionary costs. The major hypotheses can be divided into two major categories – sex is required to generate “good genes” or to eliminate “bad genes” (see chapter 1 in [Martens \(1998\)](#), [Bell \(1982\)](#)).

Good Genes – Changing Environments and the Running Red Queen

All “good genes” hypotheses state that sex can bring beneficial gene combinations and genetic changes together very fast, within a single generation, and this through the processes of meiosis, recombination and fertilisation explained above. This is the main reason why sexuals are supposed to adapt much faster to changing environments than asexuals where beneficial genetic changes need to occur subsequently in the same clone, which can take a long time (Fisher-Muller accelerated evolution; [Fisher \(1930\)](#), [Muller \(1932\)](#)) (Fig. 2).

Especially in fluctuating or heterogeneous environments, sex should be favoured (see [Schön and Martens \(2014\)](#) for more details). Changing environments can include abiotic (temperature, salinity, pH etc.) as well as biotic factors. Biotic interactions are excellent examples where fast adaptations through sex are essential, for example for hosts trying to win the arms race against their (harmful) parasites ([Hamilton, 1980](#); [Bell, 1982](#)). [Van Valen \(1973\)](#) was the first to coin the term Red Queen for this kind of interactions, referring to the book “Through the looking glass”, where the Red Queen explains to Alice that in Wonderland, it “takes all the running one can do to stay in the same place”. Biologically speaking, this means that constant adaptation of hosts is required to counter new adaptations of their virulent parasites. Despite its wide applicability, the Red Queen hypothesis on its own for explaining the paradox of sex remains controversial (see chapter 7 in [Schön et al. \(2009\)](#)) (Fig. 3).

Bad Genes – Ratchets and Hatchets

Besides generating good genes, sex and recombination have also another very important biological function, namely to quickly eliminate deleterious genetic changes or mutations from the population. Two hypotheses predict that the loss of recombination in fully asexuals will eventually lead to their extinction over longer evolutionary time frames: Muller’s ratchet ([Muller, 1964](#)) and Kondrashov’s hatchet ([Kondrashov, 1993](#)). Muller compared the loss of mutation-free (or mutation-low) genotypes in asexual populations to a ratchet, which clicks every time when such an individual is lost (by chance). The ratchet only operates in one direction, meaning that the loss of mutation-free genotypes is irreversible in asexual lineages whereas they can be restored again in sexuals every generation through meiosis and recombination. Kondrashov’s theory predicts that selection will be less effective in asexuals to eliminate deleterious mutations (see [Schön and Martens \(2014\)](#)). Both hypotheses depend on a number of factors,

Fig. 2 Sketch describing Fisher-Muller accelerated evolution as one example of the “good genes” hypothesis. Novel beneficial mutations are indicated by different capital letters. While it takes a long time in asexuals (top part of figure) before the mutations A to C occur in the same individual, this process goes very fast in sexual reproduction (lower part of figure) because of meiosis. Redrawn from Martens, K. (Ed.), (1998). Sex and Parthenogenesis, Evolutionary Ecology of Reproductive Modes in Non-Marine Ostracods. Leiden: Backhuys Publishers.

Fig. 3 Alice and the Red Queen, taking all the running they can do to stay in the same place. Illustration from “Through the Looking Glass” by Lewis Carroll 1832–98, first published 1871.

for example population size and the rate of deleterious mutations, which is why their validity can only be ultimately tested when genome-wide data on deleterious mutation rates will have become available for many different sexual and asexual animals.

Pluralistic Approaches Combining the Red Queen and Bad Genes

Up to now, no single hypothesis has been able to explain the evolutionary advantages of sex by itself but the combination of several hypotheses might do so. Asexuals should not only suffer from “bad genes” but for example also from the Red Queen (West *et al.*, 1999). Such pluralistic approaches towards solving the paradox of sex have so far mainly been evaluated theoretically through modelling and their relevance to the living worlds still remains to be tested for most asexual animals.

Novel Evolutionary Mechanisms in Asexuals to get Good Genes and Prevent Bad Genes

A Little Sex Now and Then...

As described above, at least theoretically, animals would benefit the most if they can find a way to combine the evolutionary advantages of both reproductive modes sex and asexuality. We already described several types of reproductive modes where both reproductive modes are closely linked or follow each other during seasonal cycles. Rare sex is another way to allow asexuals to persist without suffering from the consequences of “good and bad genes”. Rare sex can for example occur through kleptogenesis as described above (“Unisexual”) and is known from hermaphroditic planarians and snails, frogs and reptiles (chapters 18, 19 and 20 in Schön *et al.* (2009)). However, the incidence of rare sex in a population must still have a meaningful effect, and thresholds for such minimal effects are debatable.

Weird Sex and Horizontal Gene Transfer

While most animals undergo sexual reproduction as described in the first paragraph above, it has been postulated that other forms of genetic exchange between individuals could also allow fully asexuals to persist without true sex and meiosis. In ancient asexual bdelloid rotifers, there is recent evidence for genetic exchange between individuals, while no males have ever been observed in these animals and recent genomic data reveal genome structures that are incompatible with the occurrence of classical meiosis (Flot *et al.*, 2013). Whether this genetic exchange can be explained by a form of weird sex only known from plant species (Signorovitch *et al.*, 2015) or through non-sexual, horizontal exchange between individual rotifers (Debortoli *et al.*, 2016) as it is long known from bacteria, remains to be further tested. Several studies report that up to 9% of the genome of asexual bdelloid rotifers seems to consist of alien genes originating from bacteria, fungi, plants and other animals (e.g., Gladyshev *et al.* (2008), Flot *et al.* (2013)). Horizontal gene transfer thus provides an important potential evolutionary mechanism for asexuals to acquire “good genes” without meiosis and recombination, although it remains to be tested with genomic data how frequently it has evolved in other asexuals. Asexual root knot nematodes, for example, also have parts of their genome derived from horizontal gene transfer.

One Genotype for all

Another way for asexuals to overcome the need to constantly adapt to changing environments is to develop a so-called General Purpose Genotype, which is advantageous for survival in many different circumstances (see chapter 6 in Schön *et al.* (2009)). Ecological studies have shown that such general purpose genotypes enable ancient asexual ostracods to survive in a wide range of temperatures and salinities (chapter 11 in Schön *et al.* (2009)). Such a genotype can only stay intact in fully asexual organisms, where there is no risk that meiosis and recombination can break it up.

Multiple Copies and Genetic Copy and Repair Machines

In hybrids, the presence of two different parental genomes increases overall genetic variability and their number of potential “good genes” (see above). Many asexuals (see above) are polyploid, with several copies of the same gene. Multiple copies can considerably slow down the accumulation of deleterious mutations as described in the “bad genes” hypotheses. In a similar way, gene duplication causing the presence of multiple genes with different functions can evolve, also increasing the overall genetic variability and the “good genes”. From genomic data, it seems that such so-called gene families are very abundant in asexual cladocerans and aphids, but the influence of the asexual reproductive mode on gene duplication or even multiplication needs to be verified by comparisons with close sexual relatives.

In certain asexual groups, alternative, non-meiotic genetic mechanisms have evolved to prevent the accumulation of deleterious mutations as proposed by the “bad genes” hypotheses. Gene conversion, for example, has been described for various asexual lineages, sometimes in very high frequencies. This mechanism converts two copies of the same homologue gene that usually exist on two different chromosomes into two identical copies. This way, the copy with the deleterious mutations can be overwritten. Genome-wide data on gene conversion will hopefully become available soon, to test how widespread this mechanism is in asexual animals. Also, DNA repair, actively repairing deleterious mutations, has been proposed as a possible biochemical mechanism in ancient asexuals (see chapter 11 in Schön *et al.* (2009)) and there is some evidence for this in ancient asexual bdelloid rotifers and ostracods, which needs to be further explored (Table 1).

Table 1 Summarizing the evolutionary advantages and costs of asexual reproduction and possible mechanisms countering the disadvantages. Disadvantages of asexual reproduction are highlighted in grey. For details, see the text above

<i>Advantages of asexuality</i>	<i>Costs of obligate asexuality</i>	<i>Mechanisms countering the evolutionary costs in asexuals</i>
Fast population growth	Good genes	Mixed reproduction, a little sex
No cost of mating	Fisher-Muller accelerated evolution	Horizontal gene transfer
	Slower adaptation to changing environments	Gene expansion
		General purpose genotype
No cost of meiosis (favourable gene combinations stay together)	Red Queen	Polyploidy
Fast & efficient colonization		Hybridisation
	Bad genes	Mixed reproduction, a little sex
	Muller's ratchet	Large population size
	Kondrashov's hatchet	Gene conversion
		Polyploidy
		Hybridisation
		DNA repair

Concluding Remarks

The paradox of sex remains one of the last unsolved puzzles in evolutionary biology. In many organisms, sexual as opposed to asexual reproduction is not a black and white picture, but mixed reproduction or a link between the two reproductive modes as in unisexuality is common. Evolutionary speaking, such mixed strategies combine the advantages of both modes of reproduction, and are thus expected. There seems furthermore to be large diversity of how sex and asexuality can be combined in different animal groups. As outlined in the last paragraph, we are also just starting to comprehend how different asexuals can counter the evolutionary costs of asexuality. With the increasing availability of genomic data, also from non-model organisms, we expect that our understanding of these evolutionary mechanisms will skyrocket in the coming years.

Glossary

Allopolyploid A polyploid where selective chromosome pairing and recombination occurs during meiosis for a given chromosome (AA/BB).

Apomeiosis The avoidance of reduction in chromosome number and genetic recombination that usually occurs in meiosis.

Autonomous endosperm Spontaneous development of the endosperm without fertilization of the central cell (opposite of pseudogamy or pseudogamous endosperm development).

Autopolyploid A polyploid where all copies of a given chromosome can pair and recombine randomly in meiosis (AAAA).

Double fertilization The process by which one sperm nucleus fuses with the egg cell nucleus and the second sperm nucleus fuses with the central cell nucleus.

Endosperm The endosperm is a component of the seed which surrounds and nourishes the embryo.

Hermaphrodite An organism that contains both male and female sexual organs.

Heterosis The phenomenon that the hybrid progeny of two parents is more vigorous than both parents.

Megagametophyte The seven-celled tissue that develops from the functional megaspore, containing the egg cell and the central cell; also called female gametophyte or embryo sac.

Megaspore Mother Cell (MMC) The cell that will undergo female meiosis resulting in four megaspores.

Megaspores The products of female meiosis of which generally three degenerate and one survives.

Parthenogenesis Fertilization-independent activation of embryogenesis in an egg cell.

Pseudogamy Endosperm development relies on fertilization of the central cell (opposite of autonomous endosperm development), while the embryo is asexual due to parthenogenesis.

Sexual Reproduction in Flowering Plants

Flowering Plant Life Cycle

The great majority of flowering plants reproduce through sexual seeds, which are the result of the fusion of female and male gametes. (Fig. 1). The life cycle of flowering plants is predominantly sporophytic with a short gametophytic generation, separated by meiosis. The female gametes (egg cells) of flowering plants are formed in the ovary. The male gametes (pollen, actually the megagametophyte, see below) are formed in the anthers of the stamens. Most plant species (~95%) are hermaphrodites and produce both female and male gametes, in the same individual in the same or in different flowers.

Gamete Formation

In diploid $2n$ plants female meiosis (megasporogenesis) in the Megaspore Mother Cell (MMC) gives rise to four haploid (n) megaspores, of which three degenerate (Fig. 1). From the remaining functional megaspore, the megagametophyte (also known as female gametophyte or embryo sac) develops by three mitotic divisions, at the mature stage consisting of 8 nuclei and 7 cells (one egg cell, two synergids, one central cell and three antipodals). The two polar nuclei of the central cell fuse, and form a $2n$ nucleus. Male meiosis (microsporogenesis) produces four haploid microspores, known together as tetrads. The nucleus of the microspore divides mitotically into a vegetative and a generative cell, the latter of which divides into two sperm nuclei. The microgametophyte (pollen) is released at a bi-nucleate or tri-nucleate stage.

Double Fertilization

Pollination is the process where pollen grains land on the stigma of a plant, after transport by biotic (insects, birds or bats) or abiotic (wind or water) vectors. The pollen grain germinates and forms a pollen tube that grows into the style eventually reaching the megagametophyte. A hallmark of sexual reproduction in flowering plants is the process of double fertilization which was independently discovered by Sergei Navashin and Léon Guignard in 1898 (Van Dijk and Ellis, 2016). Of the two sperm nuclei in the pollen tube, one fertilizes the egg cell ($n + n$) and the second the central cell nucleus ($2n + n$), forming the embryo and the endosperm, respectively (Fig. 1). The endosperm nourishes the embryo and is essential for the development of the seed, but does not contribute genetically to the next generation.

Asexual Seed Production in Flowering Plants

Apomixis is a Modification of Sexual Reproduction

A relatively small number of plant species produce asexual seeds by modifying parts of sexual reproduction. These seeds are genetically identical to the mother plant. For the phenomenon in which sexual reproduction has been replaced by asexual reproduction, in 1908 Hans Winkler introduced the term "apomixis" (etymology: "apo" means "away" and "mixis" means "mixing" in Greek, hence "without mixing") (Nogler, 1984; Bicknell and Koltunow, 2004). Strictly speaking, in onions (*Allium*), bulbils (small bulblike organ of vegetative reproduction) in the inflorescence also fall under the apomixis definition. Nowadays apomixis is generally used in sensu stricto, that is, as seed-formation without gametes, thus synonymous with the term agamospermy, which is now obsolete.

Well-known apomicts are dandelions, blackberries and grasses such as Kentucky blue grass, Fig. 2 shows some common apomicts of the Compositae (Asteraceae) family. These are wild plants; apomixis does not occur in major agricultural crops, citrus being an exception.

The Discovery of Apomixis

In 1839, John Smith described three female plants of an Australian plant species *Cælebogyne ilicifolia* (now named *Alchornea ilicifolia*) that produced seeds in Kew Gardens in the absence of male plants (Van Dijk and Ellis, 2016). Other early claims of parthenogenesis could be explained by outcrossing (pollen contamination from adjacent plants) or by self-pollination (in hermaphrodites). For a long time, *Cælebogyne* was the only solid example of parthenogenesis in flowering plants – meiosis was not known in these days – until Eduard Strasburger showed that the embryos were of somatic origin and not from parthenogenetic development of the egg cell (thus no true parthenogenesis) (Van Dijk and Ellis, 2016). In 1898, Hans Oskar Juel demonstrated through cytological investigations on female plants of *Antennaria alpina* that seed development was the result of parthenogenetic development of the egg cell. Like in *Cælebogyne*, a female *Antennaria* specimen produced seeds in the absence of male plants.

Inflorescences of three apomictic species from the Compositae family, which produce clonal seeds: (A) the common dandelion (*Taraxacum officinale*), (B) orange hawkweed (*Hieracium aurantiacum*) and (C) the annual fleabane (*Erigeron annuus*). © Peter van Dijk.

Apomixis can be demonstrated in hermaphroditic plant species by using male sterile plants (excluding self-fertilization), cytological investigations (observing parthenogenesis) and marker analysis of progeny (fixed heterozygosity).

Types of Apomixis

The formation of extra somatic embryos like in the case of *Cœlebogryne* described above is called sporophytic apomixis (**Fig. 3(D)**). Another name often used is nucellar embryony, referring to the origin of the embryo in the nucellus, the tissue that surrounds the female gametophyte. In nucellar embryony, alongside the sexual embryo a seed can contain several somatic embryos, and hence this form of apomixis is often called adventitious embryony. Examples of nucellar embryony include citrus and orchids.

In gametophytic apomixis, the other main class of apomixis, a gametophyte with an egg cell is formed. To produce clonal offspring that is genetically identical to the mother plant, the avoidance of meiosis, both meiotic recombination and chromosome number reduction (apomeiosis), and the development of the embryo without fertilization of the egg cell (parthenogenesis) are required. To date, gametophytic apomixis has been demonstrated in some 300 species, which is about 0.1% of the flowering plants.

Apomeiosis and parthenogenesis take place in different cells and at different times and thus are different elements of apomixis. At low frequencies, these apomixis elements also occur in sexual plants in the form of unreduced $2n$ egg cells (giving $2n + n$ offspring after fertilization by a haploid pollen grain) and haploid parthenogenetic offspring. However, these are rare non-recurrent phenomena, as opposed to the forms of highly penetrant, recurrent apomixis described here.

Gametophytic apomixis is further subdivided into diplospory and apospory, depending on the origin of the unreduced gametophyte. Diplospory most closely resembles sexual development (**Fig. 3(B)**). Here, the normal female meiosis with recombination and reduction is replaced by a mitotic division or by a restitution of meiosis I (the first meiotic division) without recombination. Two spores are formed, one of which progresses through three mitotic divisions to form an unreduced and non-recombined gametophyte with egg cell, which is genetically identical to the mother plant. The embryo then develops through parthenogenetic activation of the unreduced egg cell. Examples of diplospory are the Compositae genera *Taraxacum* (Dandelion) and *Erigeron*, *Boechera* (Brassicaceae) and *Tripsacum* and *Eragrostis*.

In the case of apospory (**Fig. 3(C)**), an Aposporous Initial (A.I.) cell (of sporophytic origin) is formed near the sexual megagametophyte, which subsequently undergoes three mitotic divisions resulting in an unreduced embryosac, whose egg cell develops parthenogenetically. There is competition between the aposporous and the sexual gametophyte. Usually, the sexual gametophyte is not fully developed, but in some cases the sexual egg cell also develops and, in addition to the apomictic, some sexual seeds may develop (called facultative apomixis, although partial apomixis is a better term, since the sexual egg cell will develop non-parthenogenetically and the aposporous egg cell will develop parthenogenetically). Examples of genera with apospory are: *Hieracium* (Compositae); *Hypericum* (Hypericaceae), in the grasses *Poa*, *Pennisetum*, *Paspalum* and *Cenchrus*.

A rare and curious form of gametophytic apomixis is described in a conifer *Cupressus dupreziana* (not angiosperm but a gymnosperm) (Pichot *et al.*, 2001). This is a case of so-called paternal apomixis, also known as surrogate mothers. The embryos are genetically identical to the father plant, which must have produced unreduced pollen that has developed parthenogenetically. Paternal apomixis has never been reported in angiosperms, while maternal apomixis has not been observed in gymnosperms. This may be related to maternal inheritance of cytoplasmic genes in seed plants and paternal inheritance in gymnosperms. Hence maternal apomicts in gymnosperms would lack mitochondria and chloroplasts as would be the case with paternal apomicts in angiosperms.

As described above, flowering plants have double fertilization and the sexual endosperm nurses the embryo. In many apomicts, endosperm development is still dependent on fertilization. This phenomenon is called pseudogamy: pollination by the father is necessary for proper endosperm and seed development, but the father has no genetic input in the offspring. In some apomicts, especially from the Compositae family (dandelion, hawkweed, *Erigeron*), the endosperm develops autonomously from the central cell, without fertilization.

Fig. 3 Sexual and asexual reproduction in flowering plants. (a) megaspore mother cell (MMC) or megasporocyte (female meiocyte), (b) functional megaspore, (c) non-functional megaspore, (d) mature pollen grain, (e) mature megagametophyte, (f) mature sexual embryo, (g) non-recombined and unreduced functional megaspore, (h) unreduced mature megagametophyte, (i) mature unreduced embryo, (j) aposporous initial cell (sporophytic origin), (k) aposporous mature megagametophyte, (l) mature aposporous embryo, (m) nucellar cell (or other cell of sporophytic origin), (n) nucellar embryo (non-sexual embryo).

Epigenetic Reprogramming in Sexual and Apomictic Plant Species

Flowering plant germline cells are specified very late in development from somatic cells in reproductive organs, whereas mammalian germlines are specified during embryogenesis where they undergo widespread reprogramming of DNA methylation. Therefore epigenetic reprogramming in flowering plant germline cells can only take place immediately before or during reproductive development. Unlike in mice and humans, DNA methylation in the *Arabidopsis thaliana* male germline is largely maintained in CG and CHG contexts (where H=A, C or T), and only reprogrammed in CHH contexts (Kawashima and Berger, 2014). This validates work in *Arabidopsis*, *Linaria vulgaris*, and other species, that plants can inherit epialleles in a Mendelian manner. In the female *Arabidopsis* germline, inference from data collected from early embryo and endosperm stages suggests that DNA methylation is reprogrammed in the egg cell and central cell, and subsequently DNA methylation is restored during embryogenesis (Kawashima and Berger, 2014).

It is yet to be understood whether epigenetic reprogramming of the female germline occurs in apomictic species. Given that apomixis has arisen independently on many occasions it is possible that epigenetic reprogramming may occur to different extents and in different ways depending on the type of apomixis. A complete absence of epigenetic reprogramming in apomicts would lead to the accumulation of epimutations and epigenetic drift over generations which could contribute to reduced fitness and dying out of an individual clone. As gametophytic apomixis, for instance *Taraxacum*/Dandelion type diplospory, partially resembles sexual female development, it is possible that female epigenetic reprogramming may occur in a similar manner to sexual species. If female reprogramming would occur in apomicts as in sexual *Arabidopsis*, then it is unclear how apomicts overcome the requirement of pollen derived small RNAs which are thought to contribute to the re-establishment of DNA methylation in the early embryo and/or endosperm of sexual plants (Slotkin *et al.*, 2009). In contrast to gametophytic apomicts, sporophytic apomicts that do not pass through a gametophyte are probably least likely to have female reprogramming like in sexual *Arabidopsis*, but it is possible another form of epigenetic reprogramming has evolved in these species.

Correlations Between Apomixis and Other Phenomena

Apomixis and Polyploidy

In contrast to sporophytic apomixis, gametophytic apomixis is strongly associated with polyploidy. The only well documented diploid gametophytic apomict is the allodiploid apomict *Boechera holboellii* (Kantama *et al.*, 2007). The other known apomictic species are polyploid, both auto (AAAA) or allopolyploid (AA/BB). Polyploidization per se does not lead to apomixis. Many natural polyploid plant species are sexual and artificial polyploidization through colchicine treatment of diploid sexuals does not result in apomixis. Triploidy can only be maintained as the major ploidy type in a population when apomixis is present, because sexual triploids are highly infertile. Therefore natural triploid populations are always apomictic (e.g., dandelions). Theory predicts that apomicts accumulate deleterious mutations over long evolutionary time scales, because of chance events (Muller's Ratchet) or lack of effective purging of deleterious mutations (Van Dijk *et al.*, 2009). Polyploids have multiple allelic copies and are better buffered against a mutation load than diploids.

Apomicts always have living sexual diploid relatives. One reason why diploids are not apomictic may be that apomixis genetic factors are not passed through haploid pollen. In dandelions, markers linked to the diplospory allele are not transmitted through haploid pollen. A possible explanation is that recessive lethals linked to the apomixis genes are not masked in haploid pollen by sexual wild type homologs as in diploid pollen (Van Dijk *et al.*, 2009). In *Ranunculus*, *Hieracium* and *Erigeron*, for example, diploid apomicts can be made via culturing diploid microspores from tetraploid apomicts or reduced diploid egg cells of a polyploid facultative apomict (Nogler, 1984; Bicknell and Koltunow, 2004; Noyes and Wagner, 2014). In these cases a haploid life cycle phase is avoided.

Taxonomic and Phylogenetic Distribution of Apomixis

Apomixis has a broad taxonomic distribution. So far sporophytic apomixis has been found in 148 genera, apospory in 110 genera and diplospory in 68 genera (Hojsgaard *et al.*, 2014). Apomictic taxa typically form the twigs of the phylogenetic tree, suggesting that the current apomicts have arisen quite recently and that apomictic lines have a limited evolutionary life span. Assuming that apomixis in different genera originated independently, gametophytic apomixis evolved at least 178 times in the evolutionary history of the angiosperms. Most apomicts occur in the Compositae and the grass (Poaceae or Graminae) families. Sporophytic apomixis is quite common in the orchids. It is striking that in the large legume family (Fabaceae) no apomixis has been found.

Geographic Distribution

Apomicts and sexual relatives often differ in geographic distribution, a phenomenon described as "geographic parthenogenesis" by Vandel in 1928 (Hörandl, 2009). Apomicts often have a more peripheral and larger distribution than sexuals. This may be related to a better colonization ability when new territory became available in the past (e.g., at the end of the Pleistocene). In autonomous apomicts a single individual can build a new population, but for pseudogamous apomicts at least two founders are needed. Geographic parthenogenesis may also be an indirect effect of the strong correlation between apomixis and polyploidy, since sexual polyploids often have different geographic distributions than their sexual diploid relatives. Populations of apomicts are often

polyclonal with some clones being geographically widespread. For example the same dandelion apomictic clone was found in the Netherlands and in Denmark, spanning a distance of more than 600 km (Van Dijk *et al.*, 2009).

The Genetic Control of Apomixis

Most apomicts are hermaphrodites and produce both asexual seeds and sexual pollen. These pollen grains can fertilize related sexual plants and partial apomicts. Despite not knowing about the existence of apomixis, with his search for constant hybrids in hawkweeds (*Hieracium*), Gregor Mendel was the first to demonstrate that apomixis could be transferred through pollen grains (Van Dijk and Ellis, 2016).

The use of apomicts in crosses as pollen donors allows the study of the genetics of apomixis (Hand and Koltunow, 2014). In most species, apomixis appeared to be dominant to sexual reproduction, with apomicts having a simplex *Aaa* or *Aaaa* genotype thus with a single dose of genetically dominant and hemizygous apomixis factors.

The first genetic studies indicated a single locus for apomixis in which apomeiosis and parthenogenesis are jointly inherited. In later studies, especially in the Compositae family, separate unlinked loci for apomeiosis and for parthenogenesis were found. Later in some apomictic grasses uncoupling of apomeiosis and parthenogenesis was observed. It is therefore likely that the single apomixis locus found in other species contains different linked apomixis genes for different elements of apomixis.

Genetic marker studies from the late 1990s onwards showed that recombination around apomixis loci (during male meiosis) was strongly suppressed. In addition, markers in these areas were often hemizygous (only a single copy of a gene at a locus), indicating strong divergence between the sexual and the apomictic alleles. Chromosomal Fluorescent In Situ Hybridization (FISH) studies with BACs showed a hemizygous, heterochromatic Apomixis Specific Chromosomal Region (ASCR). Sequencing of apomixis locus BACs indicated that these ASCRs had a high density of transposable elements (Akiyama *et al.*, 2011).

The next step was the identification and cloning of apomixis genes. Suppression of recombination in ASCRs rendered the usual genetic map-based method unusable. Alternatively, a deletion mapping method of gamma radiation induced deletions was used in *Hieracium* (Catanach *et al.*, 2006). Deletion of the dominant apomixis alleles resulted in a reversal to sexuality, implying that sexual reproduction is default and suppressed by dominant apomixis genes. In *Pennisetum* random BACs from the ASCR were sequenced, identifying a gene homologous with BabyBoom, a known gene which causes somatic embryogenesis in *Arabidopsis* (Conner *et al.*, 2015). As in *Hieracium*, radiation-induced deletions were used in *Taraxacum*. A second EMS mutagenesis screen was used to identify via resequencing the diplospory gene within the diplospory locus.

In *Boechera*, apomixis specific gene expression was used in reproductive tissues for the identification of apomixis genes (Corral *et al.*, 2013). Association of genes with apomixis in broad wild germplasm has been used for the detection and confirmation of candidate genes in *Boechera*, *Hypericum*, *Taraxacum* and *Citrus*.

Engineering Apomixis in Sexual Plant Species

Alongside studies of apomictic species, forward and reverse genetics have been applied in sexual plants, like maize and *Arabidopsis*, to see whether apomictic-like behavior can be instigated. Interestingly, these studies have identified RNA interference (RNAi) pathway mutants as displaying apomictic characteristics. A large forward genetic screen has been carried out in maize to discover mutants that exhibit *Dominant non-reduction (dnr)* phenotypes, i.e., dominant mutations that produce unreduced egg cells. *dnr4*, one of six mutants, was mapped to a gene encoding an argonaute protein which bind to small RNAs and execute post-transcriptional and transcriptional gene silencing (PTGS and TGS) as part of the RNAi pathway (Singh *et al.*, 2011). A reverse genetic study in *Arabidopsis* has also identified mutations in *AGO9*, encoding an argonaute protein, and other genes that encode components of the RNAi pathway, that can lead to apospory like phenotypes in the female reproductive organ (Olmedo-Monfil *et al.*, 2010). The tantalizing connection between epigenetic reprogramming, RNAi and apomixis remains to be fully understood.

An alternative approach to introduce apomixis in sexual crop species is to understand the genetic and molecular basis of apomixis in natural apomicts and then use this knowledge to engineer apomixis in naturally sexual species. This approach has been successfully applied to transfer parthenogenesis from the grass *Pennisetum squamulatum* to a sexual pearl millet by way of transgenic introduction of a single BabyBoom-like gene (Conner *et al.*, 2015). This represents an important proof-of-principle that transgenic introduction of a single apomixis gene can dominantly introduce an element of apomixis in another species. Further understanding of apomixis in many different natural apomictic species will allow the development of a wide number of genetic options for apomixis engineering in crop species.

Apomixis and Plant Breeding

Introducing apomixis into sexual crop species will likely facilitate novel seed production and crop breeding approaches (Van Dijk *et al.*, 2016). For many crop species, including maize and tomato, first generation hybrids (F₁ hybrids) between two different parental lines are the most robust and highest yielding plants. The heterosis, or hybrid vigor, found in these hybrids is such that many phenotypes are markedly improved compared with either parent, i.e., they are transgressive. However, heterosis is lost in the

Fig. 4 Constant hybrid breeding. Two different inbred parental lines are crossed ($P_1 \times P_2$) to create an F_1 hybrid. The hybrid forms recombinant and reduced eggs and is pollinated by an additional parental line (P_3 *) which expresses dominant apomixis genes. The individual plants in the next generation (G_1) that contain the apomixis genes (marked with *) will reproduce asexually and can subsequently be maintained as clones in future generations allowing rapid testing of new lines.

next generations because of segregation. Practically speaking this means that seed producers must constantly generate new seed by way of sexual crosses of the two parental lines, which is an expensive process.

The introduction of engineered apomixis into sexual species like maize and tomato has the potential to remove the necessity for recurrent hybrid seed production by sexual crosses. Moreover, apomixis could facilitate the use of hybrids in crops like soybean where recurrent F_1 seed production is not currently feasible on a commercial scale due to a strong preference for self-fertilization. If a line expressing dominant apomixis genes is crossed with a non-apomictic line, then subsequent F_1 hybrids carrying the apomixis genes will reproduce as an apomict. In these F_1 hybrids the genetic information will be maintained in the same state in the next and subsequent generations. A recent study aimed to address whether apomixis in hybrids can allow true phenotypic stability. Using *Hieracium pilosella*, a natural apomictic species, apomictic hybrids between sexual and apomictic lines can be propagated a further 2 generations, and they stably maintained eighteen out of twenty traits, in eleven out of the twelve lines propagated (Sailer *et al.*, 2016). This stable phenotypic inheritance suggests that employing apomixis in agriculture is of great promise.

The introduction of apomixis in sexual plants also has the potential to significantly alter the process by which breeding is carried out. In conventional hybrid breeding where hybrid plants are used as the final crop, the genetic improvement is carried out at the level of the parental lines. In order for the hybrid of the parental lines to be consistent, the parental lines need to be inbred so that they become genetically homogenous. If the parental lines are genetically heterogeneous then the subsequent hybrids will be genetically different, and therefore will be phenotypically inconsistent which is undesirable. Constant hybrid breeding using apomixis genes, could take a different approach (Fig. 4). For instance, if an inbred line that contained apomixis genes was used to pollinate a hybrid of two different inbred lines (which would have produced a recombined and reduced egg cell) then you could produce a population of genetically heterogeneous plants that could be maintained as clones indefinitely. Phenotyping this large population and selecting the most promising plants could be quickly followed by small trials in the next generation, as all plants will be clones, and larger trials in the next generations. An additional potential advantage of introducing apomixis to sexual species is that it could guarantee seed production in the field, irrespective of weather conditions or the absence of pollinators.

The combination of apomixis breeding and simpler seed production would significantly reduce the time it takes from the original crossing of lines to being able to release a new elite variety.

Glossary

Clade A lineage of biological taxa that includes all the descendants of one common ancestor.

Direct development Laying well-yolked eggs terrestrially (including burrows, in trees, etc. Embryos develop through metamorphosis, juveniles of the adults hatch, and a free-living larval stage is absent.

Hermaphroditism The expression of both male and female reproductive function in a single individual.

Lecithotrophy Yolk is the nutrient material provided to embryos, etc., in retained eggs.

Oviparity Egg-laying.

Ovoviviparity Retention of fertilized eggs in or on the body of a parent, presumably with nourishment only from yolk, and birth at any stage of development from relatively late larva (usually into water) to fully metamorphosed juvenile.

Parthenogenesis A form of asexual reproduction in which embryos develop from an unfertilized ovum.

Placenta Organ by which fetuses obtain maternal nutrition in some species; features vascularized membranes (yolk sac, amnion, chorion) (sharks may have only the former; amniotes have all three); features close association and modification of local maternal oviductal circulation and that of the embryonic membranes.

Pseudoplacenta Organ for obtaining maternal nutrition post-yolk from the female parent; depending on the species, can be modified gills, extensions of the hindgut, etc.

Viviparity Live-birth; developing embryos retained in or on the body of a parent (usually the oviducts of the female parent), with or without post-yolk nutrients supplied by the parent, diverse means by which the fetuses obtain that nutrition (including placentas, pseudoplacentas, oral ingestion, etc.), and with birth of a fully metamorphosed juvenile (sometimes used broadly to indicate all modes of live-bearing).

Introduction

Modes of reproduction in vertebrate animals are many and diverse. Members of all of the major groups (Classes: Chondrichthyes (sharks, skates, and rays), Osteichthyes (bony fishes), Amphibia (frogs, toads, salamanders, newts, and caecilians), "Reptilia" (lizards and snakes, turtles, crocodilians, tuataras), "Aves" (birds) and Mammalia (monotremes (platypus and echidna, marsupials), and eutherian mammals)) have experimented with a number of ways of modifying eggs and sperm, and their unions, the places fertilized eggs develop, and many other features. (The reason "Reptilia" and "Aves" class names are in quotation marks is that, according to current taxonomy, some reptiles are more closely related to birds than they are to other reptiles (e.g., crocodilians are more closely related to birds than they are to lizards or turtles), so birds are included in the Class Reptilia.) The ancestral condition for vertebrates as a lineage is that reproduction occurs in water, fresh or marine; the females of the species develop and lay a relatively large number of eggs while with courting males; the males extrude sperm over the emerging eggs to fertilize them (external fertilization); then both parents abandon the egg mass so that the embryos develop and hatch into free-living, feeding larvae that subsequently metamorphose into juveniles that resemble the adults of their species. However, some to all members of each Class retain their fertilized eggs following internal fertilization (co-opting structures to transfer sperm, or developing new ones), carry the developing embryos in or on parts of their bodies for varying lengths of developmental time, and some provide nutrition to the growing embryos after they resorb their yolk, with the provision of special structures (e.g., placentas, pseudoplacentas, etc.) to provide uptake of those nutrients. The developing young, depending on the species, can be born as larvae or as fully metamorphosed juveniles. Some fishes, both marine and freshwater, and both chondrichthyans and teleost fishes, use modified fins of the males to fertilize eggs internally for the females, and teleosts, which lack the standard vertebrate oviducts, retain the fertilized eggs/embryos in the follicles or lumens of the females' ovaries until birth. Furthermore, the transition to increased terrestriality has permitted many amphibians, and of course most reptiles and all birds, to lay their eggs on land and even in trees to develop. With that increase in terrestriality, other amphibian and reptilian species, and marsupials and eutherian mammals, retain developing young in or on their bodies so that the aquatic larval stage is avoided. As they have "emerged from the water", many amphibian taxa have devised special ways of retaining their eggs – perhaps the majority of taxa keep their developing eggs/young in their oviducts, but some amphibians, especially frogs, keep their developing embryos in the stomachs of the maternal females, the vocal sacs of the fathers, pouches on the legs of the fathers, or in the skin of the back of the mothers, often in specialized pouches to contain them. Concomitantly, the developing fetuses of various species have developed ways of obtaining parental nutrition – oral ingestion, placentas, pseudoplacentas, etc. There are many different "natural experiments" among vertebrates, and some

have evolved repeatedly in different lineages in different Classes (see [Lombardi \(1998\)](#)). Brief characterizations of the major modes of reproduction in vertebrates follow and examples of the variations that have evolved among the Classes.

Oviparity

Oviparity, egg-laying, is considered to be the ancestral mode of reproduction for vertebrates. Ova (eggs) develop in the females' ovaries (in rare exceptions in males, such as a clade of toads, and pathologically in other vertebrates), mediated by such hormones as estrogen and progesterone, luteinizing hormone, etc., usually cyclically and often determined by seasonality (light, moisture, etc.). Egg sizes vary enormously, often within classes, families, and genera, but size usually characterizes each species. A major feature of egg development is vitellogenesis, the deposition of yolk in each ovum. The ancestral condition is characterized by the development of yolky eggs that are laid externally (in water or on land), often in large numbers, and fertilized externally during a diversity of forms of interactions with males. The yolk mass present in each ovum is typically sufficient to maintain the developing embryo until it hatches, when it becomes a free-living, usually aquatic, larva that can forage on its own until it metamorphoses. However, in direct-developers (see below) eggs sizes are usually large, so that the embryo is provisioned with enough yolk to carry it through metamorphosis to hatch as a juvenile. Conversely, many viviparous species (see below) have very small eggs with little yolk, correlated with their providing other forms of nutrition to the developing young (e.g., via a placenta, etc.). Numbers of eggs (clutch size) laid vary enormously; some fishes and frogs lay hundreds, even thousands, of eggs that are fertilized in water by one, sometimes more, males. While egg-laying is the ancestral condition retained by some members of all classes of vertebrates, (most fishes, most amphibians, most squamates, all turtles and crocodiles, all birds, and both species of monotremes among mammals), some are live-bearers (see below). Also, internal fertilization via a diversity of means of sperm transfer has evolved in most lineages – some fishes, using modified fins, a very few frogs, most salamanders, and all caecilians among amphibians, and all of the amniotes – those vertebrates (reptiles and birds, mammals) that surround their developing embryos with extra-embryonic membranes and then either lay the eggs/embryos or retain them in their oviducts for part or all of their development.

Viviparity

Viviparity (live-bearing) involves retaining fertilized eggs in or on a parent's body. This derived mode of reproduction is thought to have evolved in response to various stresses on free-living larvae, such as predation, limited food resources, drying, cold temperatures, etc. However, for many live-bearers the course of evolution is not clear, and certainly not the same for all. In fact, the common assumption is that live-bearers retain their internally fertilized eggs in the maternal female's oviducts; this is indeed the case in some teleost fishes, most sharks and rays, a few species of frogs and salamanders and several of caecilians, some lizards and snakes, and nearly all mammals. However, teleost fishes lack complete oviducts, and retain developing young in the follicles or the lumens of the ovaries and in one group (seahorses and relatives) the males retain the developing young in special abdominal pouches, and some frogs retain the eggs in pouches on the females' backs, in her stomach, or even in the vocal sacs or leg pouches of the male parents. In these frog examples, the eggs are fertilized externally, and the male either kicks the eggs into the back pouches of the female, or one of the parents turns and ingests the newly fertilized eggs – either the mom depositing the eggs in her stomach (the species is recently extinct, so the mechanism by which the developing young are retained without being digested is not known, save for evidence that the young secrete a prostaglandin that inhibits stomach acid production by the female) or the dad in his vocal sacs. Retention in squamate reptiles and in nearly all mammals is in the females' oviducts, at least for some time. Retention of eggs in oviducts and maintenance through to a juvenile state seems to be easy to do. Some estimates indicate that it has evolved more than 100 times in squamate reptiles; however, recent phylogenetic analyses question that number. Retention can occur either with the yolk being the only (or main) maternal nutrient provided, or with the maternal (rarely, but occasionally, the male) providing nutrients after the yolk is resorbed (see [Section Ovoviviparity](#)). Various mechanisms for provision of nutrients and their uptake by the developing young have evolved. Neither teleost fishes nor amphibians have placentas, at least in the sense of their being composed of extra-embryonic membranes. Some teleost fishes develop extensions of the hind part of the intestine or the gills that are highly vascularized and apparently used for nutrient uptake as well as gaseous exchange ([Wourms and Lombardi, 1992](#)). Among a very few frogs and salamanders, but several caecilians, the oviductal lining cells elaborate a nutrient material that the juveniles, hatched after their yolk is resorbed, ingest orally before birth, often using fetal teeth. It also has been suggested that the gills, tails, and skins of viviparous amphibians might be involved in nutrient uptake, but this has not been confirmed. The gestation period in amphibians varies according to species, but apparently is tied to seasonal/ecological variables, such as rain periods, temperature, and prey abundance. Both the obligately viviparous frog and salamander live at high altitudes, the frog on Mt. Nimba in Africa, the salamander in the Alps. Their reproductive periodicity is very different, however; the frog's gestation is 9 months long, and its endocrinology and embryonic development are specifically controlled in response to temperature and moisture. In contrast, the gestation period for the salamander can be anywhere from a few months to 4 or 5 years, apparently depending on the extremity of the cold of the winter seasons. Subspecies of a salamander have an important form of maternal nutrition in that oviductal embryos at a somewhat advanced stage of development are cannibalistic: they eat sibling eggs and often less-well developed embryos while in the oviduct, and the cannibals are born fully metamorphosed. This constitutes an unusual form of maternal nutrition (summarized by [Wake \(2015\)](#)). Some sharks and rays, and marsupials, at least early in development, employ the highly

vascularize yolk sac as a nutrient-accessing placenta. The placenta of squamate reptiles, many marsupials, and all eutherian mammals is composed of various arrangements of the amniotic and chorionic membranes, and associated assembly of the area of the oviduct in which the young develop (usually termed the uterus). In fact, although there are some differences in the relationship of the yolk, etc., the evolution of placental organization is very similar among squamates and eutherians. New information about the genetics of placental development and maintenance, first found among mammals, but now also occurring in squamates and seahorses, indicates that a common genetic basis exists in all of these diverse vertebrates for intra-oviductal maintenance, especially placentae. Typically, in the species in which the mother provides nutrients during gestation for a time after the yolk has been resorbed, it is correlated with the eggs having been provisioned with reduced amounts of yolk – the system has evolved such that the maternal nutrient contribution is a limited amount of yolk, followed by nutrition via oviductal secretion or via placentation for vascular provision (see [Blackburn \(2015\)](#), for a summary of the evolution of vertebrate viviparity).

Ovoviviparity

Ovoviviparity is a term that has been used to characterize a diversity of features in a diversity of taxa. It generally refers to modes of fertilized egg retention, often with live birth, such as egg retention but with eggs laid (some fishes, amphibians, reptiles, but usually considered a form of oviparity, in that eggs are laid), aplacental viviparity (as in certain elasmobranchs, teleosts, amphibians), pseudoviviparity (some teleost fishes), lecithotrophy (yolk nutrition of the retained developing young, without provision of post-yolk-resorption nutrients) as in some elasmobranchs, teleosts, amphibians, and reptiles. Some researchers use “ovoviviparity” to mean any of these conditions and the inherent discrepancies and even contradictions, largely because of differing assumptions and lack of coherent definition of the precise meaning of the term for the taxa studied ([Lodi, 2012](#)). Much of the difficulty is removed by explicit definition, as well as the recognition that a more precise term may be better applied to specific taxa and cases. For example, is a snake that lays eggs that hatch within 24 h of laying oviparous, despite the long-term (developmentally) egg retention? Is the snake whose eggshell breaks down 24 h before birth such that a juvenile is born clearly viviparous? In a strict sense, the answer is “yes”, but the terms do not give real clues as to the reproductive pattern. I find that a careful definition of “ovoviviparous” that includes two criteria: retention of ova with investments of yolk but no other provision of parental nutrition, and birth of free-living, autonomous offspring at virtually any stage of development, from early larva to fully metamorphosed young (often still with vestiges of yolk in the gut) is most appropriate. This definition of “ovoviviparity” then requires that taxa with the presence of aplacental or placental maternal nutrition and genetically/physiologically “fixed” birth following the completion of metamorphosis be considered “viviparous” because of the combination of these two characteristics. These definitions of ovoviviparity and viviparity work most usefully for live-bearing amphibians, in which the two features clearly distinguish the reproductive modes. Apparently all live-bearing frogs and salamanders, except one species each (see [Section Viviparity](#)), are ovoviviparous – yolk is the nutrient material. Reports of possible nutrient uptake in a few species still require demonstration of nutrient value of secretions of the paternal vocal sac in the former and the dorsal brood pouch in the latter. Two distantly related clades of frogs have evolved a similarly complex mode of ovoviviparity that involves a particular kind of courtship, followed by egg-laying and spermiation, then with the male parent kicking the fertilized eggs up onto the back of the maternal parent. Members of the genus *Pipa* in the aquatic New World family Pipidae have a complexly specific courtship that ends with the vent of the male appressed to that of the female so that sperm are deposited as each egg is delivered. The pair stays in copulation during the period of egg deposition and the male kicks them onto the back of the female that he is clasping. The female’s skin has proliferated and become highly vascularized owing to her reproductive hormones (estrogen and progesterone), so that the eggs lie in cups of skin tissue. The cups deepen as the embryos develop. The embryos in some species leave the parent’s back as late larvae and complete metamorphosis in streams or ponds, while in other species they are born as fully metamorphosed froglets. The other clade that has evolved back-brooding is even more complex. In the genus *Gastrotheca* in the terrestrial New World family Hemiphractidae, the female parent develops a pouch composed of the folded skin of her back into which the father frog, at the end of courtship, kicks each egg into the opening of the pouch. The pouch develops early in the life of the female in response to estrogen, and at breeding time proliferates and vascularizes as her estrogen and progesterone concomitantly accelerate egg development and ovulation. In some of the more than 100 species, the embryos reach a late-tadpole stage and emerge from the pouch into water to complete development (whereupon they assume a terrestrial life); in other species, the embryos are born as fully metamorphosed froglets, obviating any need for an aquatic larval period (summarized by [Wake \(2015\)](#)). The evolutionary convergence between the aquatic pipids and the terrestrial *Gastrotheca* is striking!

Direct Development

Direct development is a term sometimes used to indicate all forms of development in which a free-living, usually feeding, pre-metamorphic larval stage is absent, such that it thereby includes all forms of live-bearing. However, most researchers on vertebrate taxa use a more restricted definition of direct development, such that it is the condition in which eggs are laid on land, and development through metamorphosis occurs before hatching with fully developed juveniles emerging. This mode of development characterizes several lineages of frogs, salamanders, and caecilians. The elimination of a biphasic life cycle via this mode is considered to be a component of the evolution of terrestriality. The eggs are usually externally fertilized, and range in number between 4 or 5 and more than 100, depending on the species. The eggs are usually larger than those of biphasic relatives, owing to

the provision of a large yolk mass to nourish the embryos through metamorphosis. The term “direct development”, in this sense, is rarely (if ever) used for amniotes: egg-laying turtles, crocodilians, squamates, and birds that lay eggs on land that hatch as autonomous juveniles, even though post-hatching parental provisioning might be needed (e.g., in birds that are fed by parents for a time), or mammals.

Hermaphroditism

Among vertebrates, hermaphroditism, the expression of both male and female reproductive function in a single individual, is found only in teleost fishes and in frogs (the instances reported for other vertebrates are considered pathologies, as are those in some species of fishes and frogs). Hermaphroditism takes many forms – the distinction between functional and non-functional hermaphroditism is a major one. Hermaphroditism is usually identified by gonad morphology; there are three main groups or categories. One is synchronous hermaphrodites, in which mature testicular and ovarian tissues are present at the same time, and both produce sperm and ova, respectively. Typically, they are fishes that form spawning pairs, and one initially spawns eggs and the other fertilizes them, then the “fertilizer” deposits its eggs and the other fish fertilizes them, such that both fishes perform both “male” and “female” roles. In other hermaphrodites, the gonads have both ovum-producing and sperm-producing areas, but one or the other predominates during different phases. Sex change is genetically programmed. “Female first” (protogynous) species lay eggs initially, then shift to testis-dominance and sperm deposition. “Male first” (protandrous) species are the opposite, depositing sperm initially and shifting to egg development and deposition. Both types have a transitional period in which the gonads exhibit fairly well-developed ovarian and testicular tissues. Functional hermaphroditism is reported in several families of teleosts. It is most prevalent in tropical marine perciforms, in which it has evolved in 16 genera (including seahorses, gobies, damselfishes, parrotfishes, and wrasses), but it occurs in eels in two orders as well as in diverse members of other clades. Hermaphroditism is found almost exclusively in marine fishes; synbranchid eels are the only fresh water forms for which hermaphroditism has been documented. Highly speciose freshwater families do not include any confirmed instances of hermaphroditism, although they have evolved diverse morphologies and ecologies. Some frogs, especially bufonid toads, have long been known to have ovarian components associated with the testes of presumably male animals. The ova that are produced are usually resorbed. In a few species of frogs, old females sometimes reduce their ovaries and testicular tissue develops, occasionally producing mature sperm; typically, apparently female frogs have well developed ovaries and oviducts, and less well developed testicular tissue and sometimes seminal vesicles. Recently, evidence has shown that many species of frogs are affected by exposure to herbicides during their development such that they are demasculinized, with reduced testes and testosterone production, developing ovaries, modified larynges, and incapability of reproduction. The same phenomenon has been reported in several species of fishes as well, and attributed to consequences of runoff of agricultural water into natural streams and rivers. Furthermore, such induced hermaphroditism appears to be increasing world-wide, correlated with agricultural use of herbicides and other endocrine disruptors (see [Avisé \(2011\)](#)).

Parthenogenesis

Parthenogenesis is reproduction without fertilization, an ovum developing into a new individual without fertilization by a sperm. In vertebrates, parthenogenetic “species” are the result of modification of ovum development, usually changes in meiosis, leading to eggs produced with multiple sets of chromosomes. Some species are facultatively parthenogenetic, induced to produce asexually as ova that have undergone “meiotic error” are laid and develop into adults, but these females usually are sterile and cannot produce a new generation of offspring. They typically are evolutionary/ecological modifications of species that have “standard” reproductive modes, but have hybridized or undergone other speciation modes. In some cases, courtship by a male of a closely related species is required to induce ovum development, but his sperm do not fertilize the ovum. Often, this mode of reproduction produces all-female species, given that only ova develop. Consequently the broods of young are effectively clones of the mother. Several species of teleost fishes, at least three sharks, several lizards, a snake, and frogs and salamanders are known to be strictly parthenogenetic, while yet others are considered facultative or incomplete parthenogens. There are no known cases of natural parthenogenesis in mammals, but it has been artificially induced in rabbits, mice, pigs, and monkeys, often with consequent abnormal development. The low genetic variation and modification of size and other components of development typically cause reduced fitness of offspring in parthenogenetic species. The patterns of evolution of various forms of natural parthenogenesis in several vertebrates have been studied, and are diverse and complex (summarized by [Avisé \(2008\)](#)).

The complexity, variation, and frequent convergences of the evolution of vertebrate reproductive modes is exciting, and not yet fully understood.

Glossary

Arginine vasotocin (AVT) Nine amino acid neuropeptide that is the homologue of arginine vasopressin found in mammals. These hormones are released at the posterior pituitary gland, but also widely in the brain where they act as neuromodulators.

Aromatase Enzyme that is a member of the cytochrome P450 family of proteins and plays a key role in the biosynthesis of estrogens through metabolism of androgens such as testosterone. Teleost fishes exhibit two forms of aromatase produced from distinct genes and that are primarily active in the gonad and brain respectively.

Estradiol 17 β (E₂) The most important circulating estrogen in both teleost fishes and mammals, produced in the ovaries but also other tissues including brain through the action of the enzyme aromatase.

Gonadotropin Releasing Hormone (GnRH) Ten amino acid neuropeptide hormone produced in the preoptic area of the hypothalamus in fishes that sits 'atop' the hypothalamo-pituitary-gonadal axis; it is released at the anterior pituitary gland to regulate gonadotropin secretion and is a key regulator of reproduction.

Gonochorism A sexual pattern in which individuals mature as one sex and remain that sex.

Initial phase The first sexual phenotype seen in many protogynous species, often characterized by relatively drab colors and relatively low displays of aggression and courtship behavior.

11-Ketotestosterone (11KT) Potent androgenic steroid hormone in teleost fishes that is analogous to dihydrotestosterone in tetrapod vertebrates in terms of inducing the development of secondary sexual characters often associated with territoriality and courtship in large males.

Monoamine neurotransmitters These are important neural signaling molecules characterized by having an amino group connected to an aromatic ring. Important examples include serotonin, dopamine, and norepinephrine.

Oviparity A mode of reproduction in which females produce eggs that develop outside of the female's body.

Protandry A sexual pattern in which individuals mature as males and can then later change functional sex to become female.

Protogyny A sexual pattern in which individuals can mature as females and then later change functional sex to become secondary males. In *monandric* ('one male') protogyny, all secondary males first pass through a female stage. In *diandric* ('two males') protogyny, individuals can mature as either males or females and both can change from the initial phase (IP) to become the larger and typically colorful and aggressive terminal phase (TP) males.

Simultaneous Hermaphroditism A sexual pattern characterized by individuals possessing both mature ovarian and spermatogenic tissue within the same functional gonad.

Steroid receptors Steroid hormones act largely through intracellular steroid receptor proteins that bind hormone and then function as 'ligand activated transcription factors' to regulate gene expression in target cells. Teleosts have multiple forms of both the estrogen and androgen receptors.

Testosterone (T) Important androgenic steroid hormone in all classes of vertebrates; critically, this steroid often functions as a biosynthetic intermediate in estradiol or 11-ketotestosterone production.

Viviparity A mode of reproduction in which the fertilized eggs develop within the body of the female and offspring are born live.

Introduction

This article addresses modes of reproduction in fishes generally with an emphasis on one of the more dramatic examples of reproductive adaptation to social environment seen in fishes and, indeed, any animal – socially controlled functional sex change. Fishes show the broadest range of sexual patterns of any group of vertebrates. With respect to sex determination, this variation includes all-female unisexual species. Within sexual species, these patterns range from strict gonochorism where sex is determined by sex chromosomes to simultaneous hermaphroditism where individuals can alternate male and female function on a second-to-second basis. Between these extremes are species where:

- i) Sex is determined by social or physical factors prior to maturation, but then sex is fixed after maturation;
- ii) Species that mature as one sex, either male or female, and then change to become the other sex following maturation either as part of an ontogenetic sequence dependent on age or body size or in response to changes in their social environment; and
- iii) Species that can undergo serial adult sex changes in both directions in response to social environment.

In addition to variation in sex determination patterns, fishes also exhibit variation in terms of whether fertilization occurs externally or internally and whether the offspring develop inside or outside of the mother. Most fishes exhibit external fertilization in which females release either negatively buoyant eggs onto a substratum (e.g., rock, sand, or underwater vegetation) or

positively-buoyant eggs that instead undergo early development while floating in the water column. These floating eggs and typically later planktonic larvae can often be transported considerable distances from the location where they were fertilized by currents, particularly in large lakes and oceanic environments.

External fertilization involves the release of eggs by females and the development of these eggs externally is a pattern referred to as oviparity. Viviparity instead refers to the pattern where embryonic development occurs inside the female. For sexually-reproducing species, this is associated with internal fertilization. A full description of the variation across fishes is beyond the scope of this article, but the well-studied Poeciliid fishes illustrate viviparity and some of the variation that occurs within this pattern well. Poeciliid fishes, of which the guppy is a familiar example, are a speciose group of freshwater fishes originally found in Africa and tropical and warm temperate zones of North and South America, but which have now been introduced very widely around the world. Male poeciliids have an intromittent organ termed the gonopodium that used to transfer sperm to females during copulation. Development of embryos occurs internally and the young are born live as free-swimming juveniles. Interestingly, there is considerable variation in the degree to which embryos are provisioned with nutrients before fertilization (*lecithotrophy*) versus after fertilization through maternal transfer (*matrotrophy*) in these live-bearing species and even within closely related groups such as the genus *Poeciliopsis*. Matrotrophy involves development of a placental structure and can account for the bulk of nutrients contributing to embryonic growth in some poeciliid species. This variation in a complex reproductive trait across the Poeciliid fishes has made it a particularly interesting group for addressing the evolution of reproductive modes (see Pollux *et al.*, 2009).

Socially-Controlled Sex Change

The remainder of this article focuses on sex change in adult fishes. Many species that undergo sex change also exhibit alternate male phenotypes and these are fascinating reproductive adaptations, but a full treatment is beyond the scope of this article.

Sex change provides a useful natural experiment for understanding basic processes of sex determination and differentiation because key developmental events take place in manipulable adult animals. However, understanding sex change is also important from a practical perspective as many commercially important fish change sex. The adaptive significance, or 'why?', of sex change is generally better understood than the developmental and physiological mechanisms that underlie this process (i.e., 'how?'). When individuals can reproduce more effectively as one sex when small or young and as the other sex when larger or older, there is an obvious benefit from being able to change sex to maximize reproductive success for their body size. This is known as the 'Size Advantage Model' of sex change and it has been quite successful in explaining patterns of sex change in many species. Other models include the Low Density Model and high dispersal models, in which sex change offers an advantage to species in which the opportunity to encounter an individual of the opposite sex is rare.

While the Size Advantage model and other models offers a compelling explanation for the presence of sex change in many species of fishes where this pattern is observed, it is equally striking that many species exhibit similar patterns of reproductive success across body size (especially mating advantages for large males) and would be predicted to exhibit sex change according to the model, yet do not. This is true both within the fishes and especially for other vertebrate groups where sexual lability is both much rarer and restricted to early developmental periods if it occurs. What accounts for this variation?

In mammals, the sex of an individual is determined by sex chromosomes at fertilization and specifically the presence or absence of the gene SRY (for 'Sex determining Region of the Y chromosome'). The testis or ovaries then arise relatively early in development and their hormonal secretions (particularly testicular androgens) organize other tissues including the brain. By contrast, the gonads develop relatively late in fishes as compared with other tissues and often well after individuals have spent considerable time as independently living 'miniature adults'. Why does this matter in terms of environmental control of sex determination?

When the gonads develop very early, the brain is neither capable nor has the opportunity to gather and interpret environmental information that might be used to adaptively guide sex determination. By contrast, fishes often have ample opportunity to collect such information prior to gonadal development and, in the case of social influences, possess a well-developed brain to interpret it.

Socially controlled sex change was first described and is best characterized in tropical marine fishes associated with coral reefs. This is because sex change is relatively common in four families that are conspicuous and important parts of the fish community on reefs. These families are the wrasses (Labridae), parrotfishes (Scaridae), damselfishes (Pomacentridae including the anemonefishes, subfamily Amphiprioninae), and the gobies (Gobiidae). Socially controlled sex change is also found in some temperate species where studies have focused on wrasses and gobies.

Male-to-female adult sex change is termed protandry and is seen in several families of fishes. Socially controlled protandry is best described in the anemonefishes, an Indo-Pacific group of 26 species (25 in *Amphiprion* and one species of *Premnas*). The anemonefishes have been an object of fascination due to the symbiotic relationship they show with large tropical sea anemones and as stars in the movie *Finding Nemo* that featured Nemo, a 'boy' anemonefish, being raised by his single father Marvin. However, had the movie been biologically accurate, Nemo's father would have likely changed sex to become female following the disappearance of Nemo's mother and Nemo would have been like other anemonefishes, developing as an immature female who would likely have matured into a functional male to form a breeding pair in the social group (Fig. 1). This pattern of a breeding pair and up to several immature females forming social groups has now been described for several anemonefish species. The gonadal structure of males consists of peripheral active spermatogenic tissues surrounding immature ovarian tissue (oocytes in the previtellogenic stage of development, Fig. 2). This pattern is interesting because it illustrates the fundamentally 'female first' pattern

Fig. 1 Sexual patterns in fishes.

of development in sex changing fishes even when the adult sex change pattern is male-to-female (we can only speculate as to why the movie makers decided not to have Nemo's father change sex!).

The maturation of juveniles and sex change by breeding males appears to be prevented by aggressive dominance of large females in anemonefish. In the cinnamon anemonefish *Amphiprion melanopus*, dominant females rapidly and aggressively approach their male pair mates approximately 150 times a day. Disappearance or experimental removal of these females eliminates this inhibition and both the behavior and gonadal structure of the male begins to change rapidly. Male cinnamon anemonefish made experimentally dominant show significant increases in aggressive behavior within one day of the removal of their dominant female pair mates and extensive changes in gonadal structure with proliferation of oogonial like cells by ten days later. Replacement of spermatogenic tissue with ovarian tissue is complete by 20 days into the process.

The most common form of socially mediated sexual plasticity seen in reef fishes is female-to-male sex change or protogyny. Protogyny can take two forms. In monandric ('one male') protogyny, all individuals mature as females and only later potentially change to become males. In diandric protogyny, individuals develop initially as immature females, but may mature into the 'initial phase' (IP) as either males or females and either of these phenotypes can then undergo change to the typically brightly colored terminal phase males later (Figs. 1 and 3). Monandric protogyny occurs in some damselfishes (Pomacentridae) and is common in gobies and groupers with both monandric and diandric protogyny occurring in wrasses and parrotfishes. As predicted by the Size Advantage model discussed earlier, the adaptive significance of both monandric and diandric protogyny appears to be the high levels of reproductive success that accrue to large males who can monopolize access to females or spawning territories.

Perhaps the most dramatic examples of sexual plasticity are seen in gobies and some serranid fishes. A number of serranid species are simultaneous hermaphrodites, maintaining both mature ovarian and testicular tissue in the same gonad. The hamlets (genus *Hypoplectrus*) are native to the Caribbean Sea and alternate female and male behavior and spawning on a second-to-second time scale in a behavior termed 'egg trading'. Other species of small serranid sea basses maintain gonads with mature tissue of both sexes and may lose the ovarian tissue when they become socially dominant members of social groups able to monopolize mating.

A number of goby species are protogynous as discussed above for other families. However, gobies also show an additional degree of flexibility in species that exhibit bi-directional sex change. Species of *Gobiodon* and *Paragobiodon* are obligate residents of branching corals in the west Pacific that can change sex in either direction. This flexibility allows any two individuals to form a mating pair on a coral, likely a strong advantage for a very small-bodied species in which traveling large reef areas in search of mates could be very dangerous.

Steroid Hormone Patterns in Sex Changing Fishes

The effects of androgens in a sex changing species were examined as early as 1962 in the wrasse *Coris julis*, but measurements of circulating levels of sex steroid hormones had to wait for development of a technique termed 'radioimmunoassay' (RIA). Early studies using RIA showed that plasma levels of the primary estrogen in fishes (and mammals) 17-beta-estradiol (E_2) were elevated in female saddleback wrasses and declined dramatically at the onset of sex change at the same time that oocytes in the gonad degenerated (Fig. 4). Levels of E_2 remained very low across sex change and in terminal phase (TP) males. By contrast, a key

Fig. 2 Gonad structure in the anemonefish *Amphiprion melanopus* for juvenile non-breeders (A), breeding males (B), breeding females (C), and a sex changing fish ten days after removal of the dominant female (D) – low magnification, (E) – higher magnification. OO, presumptive oogonia appearing as ovary develops during sex change; PO, previtellogenic oocyte; SP, spermatogenic tissue (multiple stages); SZ, spermatozoa. Micrographs originally appeared in Godwin, J., 1994. Histological aspects of protandrous sex-change in the anemonefish *Amphiprion melanopus* (Pomacentridae, Teleostei). *Journal of Zoology* 232. 199–213.

androgen in fishes 11-ketotestosterone (11KT) was present at low levels in females and across sex change, only becoming elevated in TP males. Importantly, significant increases over female 11KT levels appeared to follow rather than precede or accompany the appearance of mature spermatogenic tissues. Similar sex steroid hormone patterns are seen in the stoplight parrotfish (*Sparisoma viride*) and several other sex changing species that have been examined, including goby and grouper species. In an interesting twist, the anemonefish *Amphiprion melanopus* also shows higher plasma E_2 levels in females and higher 11KT levels in males despite the direction of sex change being male-to-female and females being the larger and aggressively dominant sex (Fig. 5). A study in the protogynous bluebanded goby *Lythrypnus dalli* show a positive correlation between androgen levels and aggression in dominant females, but only when the male was removed from the social group, indicating that androgens may be responsible for inducing behavioral changes associated with female to male sex change.

The role of steroid hormones in the control of sex change is supported by many experiments manipulating either steroid hormones directly or their synthesis. Androgen administration is effective for inducing male sex determination in a wide range of fishes and this approach is widely used in aquaculture to produce faster-growing males. Beginning in 1955 with bluehead wrasses, androgen administration has also been used to successfully induce sex change in a number of sex-changing species. These include a number of wrasses, the stoplight parrotfish *S. viride*, the blackeye goby *Coryphopterus nicholsi*, and several species of groupers.

Fig. 3 Initial phase (top) and terminal phase males (bottom) of the bluehead wrasse, *Thalassoma bifasciatum*.

Blocking estrogen synthesis has similar effects to androgen administration in inducing female-to-male sex change. A key regulatory step in estrogen synthesis is at the enzyme aromatase, a member of the cytochrome P450 family of proteins. Fishes express two forms of this enzyme, known as gonadal and brain aromatase. Aromatase and estrogens generally appear to play key roles in sex determination in a range of species. Manipulations of estrogen signaling and aromatase activity are effective in manipulating the occurrence of sex change in several wrasses and grouper species as well as two goby species. For example, inhibiting aromatase action in the blackeye goby *C. nicholsi* induces sex change as effectively as 11KT implants. A recent experiment successfully induced sex change in the protogynous greasy grouper, *Epinephelus tauvina*, through administration of 17-methyl testosterone and an aromatase inhibitor and studies have indicated that gonadotropins modulate the androgen increase in that triggers sex change in the dusky grouper, *Epinephelus marginatus*.

The bi-directionally sex changing gobies in the genus *Gobiodon* are especially interesting in this respect. As noted above, these gobies can change sex in either direction to form heterosexual pairs on the corals where they reside. Implants of the aromatase inhibitor fadrozole induce females to become males and males to remain male even when paired with a larger male. Conversely, E_2 implants induce sex change in males paired with other males while E_2 -implanted females paired with other females did not change sex. Also consistent with a dominant role for estrogenic signaling in regulating sex change was a study where co-administering E_2 with androgens in threespot wrasses blocked the female-to-male sex change that would otherwise occur. In bluehead wrasses, E_2 implants prevented behavioral sex change in large females even when removal of more dominant fish created a socially permissive environment that normally promotes sex change. Taken together, these studies suggest estrogenic inhibition may be the critical controlling factor for gonadal sex change.

The environmental cues for socially controlled sex change must clearly first be perceived in the brain. Consistent with this expectation, the more rapid decreases in aromatase activity seen in the brain compared to the ovaries of sex changing *Lythrypnus dalli* gobies suggest a key early event in the sex change process is reduced estrogen signaling to neural structures.

Fig. 4 Relative steroid hormone levels in plasma of saddleback wrasses shown for natural females and TP males as well as females undergoing socially-induced sex change in experimental pens. Redrawn from Nakamura, M., 2005. Sex change in coral reef fish. *Fish Physiology and Biochemistry* 31, 117.

Fig. 5 Relative steroid hormone levels in plasma of the anemonefish *Amphiprion melanopus* in natural males and females and as males underwent protandrous sex change following experimental female removals from social groups. Relative levels of different hormones are depicted approximately to scale except for cortisol, where levels were substantially higher. Redrawn from Godwin, J.R., Thomas, P., 1993. Sex change and steroid profiles in the protandrous anemonefish *Amphiprion melanopus* (Pomacentridae, Teleostei). *General and Comparative Endocrinology* 91(2), 144–157.

Other Steroid Hormones and Sex Change

Because the social regulation of sex change is often closely related to aggressive behavioral dominance, there has also been interest in the potential role of stress hormones. The key stress-related steroid in fishes is cortisol, as in humans, which is synthesized in the interrenal gland. Subordinate social status is quite often characterized by elevated cortisol levels in fishes and other species and elevated cortisol levels can also inhibit reproductive function. However, newly dominant and sex-changing anemonefish (*A. melanopus*) and bluebanded gobies actually show increases in cortisol levels during the sex change process. This led Solomon-Lane and colleagues to propose glucocorticoid signaling plays an important role in this process as with other examples of developmental transitions in vertebrates. Interestingly and consistent with this suggestion, prolonged administration of cortisol to female three-spot wrasses induced sex change, potentially by causing a decrease in the estrogen level that leads to sex change. However, stress effects can be exquisitely time sensitive and animals show physiological adaptation to chronic stressors in sometimes subtle ways, so more work remains to be done regarding the potential role of the endocrine stress axis in mediating sex change.

Neural Mechanisms of Sex Change

It has become clear that the often dramatic changes in behavior that accompany sex change are key parts of the change in sexual phenotype and may play an important role in stimulating the gonadal sex change process. This appreciation of the role of behavioral change as well as development of new techniques have shifted much of the focus in recent studies of sex change to neural and neuroendocrine mechanisms that may translate changes in social environment to changes in the gonads and other parts of the sexual phenotype.

The hypothalamus serves as a critical integrative center for both the reproductive axis and sexual behavior and is the site of gonadotropin-releasing hormone (GnRH) neurons which project to the pituitary gland. This brain region has therefore been a logical starting point for investigations of the neural mediation of sex change. Both correlative and experimental approaches support a role for the GnRH system in the sex change process. Working with bluehead wrasses in the early 1990s, Matthew Grober and colleagues described greater numbers of immunoreactive GnRH neurons in the hypothalamus of TP males than in that of females and that these numbers were increased in females by 11KT treatment. This pattern of greater numbers of GnRH neurons in males than females is also seen in the Ballan wrasse (*Labrus berggylta*) and in the protandrous anemonefish *Amphiprion bicinctus* (despite females being larger and aggressively dominant in anemonefishes). Expression of GnRH has not been closely monitored through the sex change process in any species, but findings from the cichlid *Astatotilapia burtoni* suggest this would likely be informative. This species shows socially regulated sexual development that involves rapid activation of preoptic area GnRH neurons when changes in social conditions are perceived. This rapid activation of GnRH neurons underlies the rapid activation of the HPG axis when subordinate males ascend to social dominance.

What mechanisms might induce a change in the activity of GnRH neurons? Changes in neural estrogen signaling due to reductions in brain aromatase activity at the onset of sex change and a potential role for stress hormones were discussed above. Another intriguing possibility is the monoamine neurotransmitters – serotonin, noradrenaline, and dopamine which vary in key forebrain areas across sex change in the saddleback wrasse with manipulative experiments further supporting this role. The neuropeptide hormone arginine vasotocin may also be important as studies in the grouper *Epinephelus adscensionis* revealed co-localization of AVT and GnRH in the preoptic area of the hypothalamus. Further studies have indicated that a related hormone, gonadotropin inhibitory hormone (GnIH) may also play an important role in the regulation of sex reversal, potentially by affecting GnRH signaling.

Before leaving the discussion of neural mediation of gonadal sex change, we discuss a study suggesting that variation in target tissue responsiveness to gonadotropins regulates sex change. The bidirectionally sex changing goby *Trimma okinawae* expresses both ovarian and testicular tissues, but with only one type being mature and active at a given time. Kobayashi and colleagues found that the active portion of the gonad expressed gonadotropin receptors at much higher levels than the inactive portion and that this higher expression was associated with greater responsiveness to gonadotropin. Exposure to visual cues that induce a change to the opposite sex also reversed the pattern of gonadotropin receptor expression within approximately twelve hours.

Neural Bases of Behavioral Sex Change

Successful sex change requires coordinated changes in a suite of phenotypic features. Behavioral sex change is often very rapid, occurring within one to several days in anemonefishes and blue banded gobies and within minutes of dominant male removal with cleaner and bluehead wrasses studied in nature. This short time scale suggests gonadal change does not drive behavioral change. Indeed, the reverse may be true. The role of the gonads, neural mediators of behavioral sex change, and potential connections between the behavioral and gonadal sex change are discussed in this section.

Surgically removing the gonads from female bluehead wrasses does not prevent behavioral sex change when those females are made socially dominant. While the gonads are not necessary for the behavioral components of sex change in this species, ovariectomized females do not develop TP male coloration on becoming dominant. This is presumably because they lack a source of 11KT, which is critical for male morphological secondary sexual characters. This lack of necessity for gonads in behavioral sex

Fig. 6 Social status influences AVT mRNA levels in the preoptic area of the hypothalamus in bluehead wrasses while gonadal status does not. Dominant individuals were the largest in their social groups while subordinates were not. Intact animals underwent 'sham' operations to control for the surgical procedure. Inset shows AVT mRNA in the preoptic area visualized by the technique of in situ hybridization. Data from Semsar, K., Godwin, J., 2003. Social influences on the arginine vasotocin system are independent of gonads in a sex-changing fish. *Journal of Neuroscience* 23, 4386–4393.

change is generally consistent with often very rapid time course of this process and highlights the fact that important changes in steroid hormone signaling do not need to occur in the gonad itself.

What neural mechanisms do mediate behavioral changes during the sex change process? Two areas of focus have been monoamine neurotransmitters and neuropeptide hormones. Changes in monoamines were mentioned above and in saddleback wrasses (*T. duperrey*) changes are especially pronounced during the first week of sex change when social dominance for sex changing females is being established. During the first week in experimental groups, dominance interactions develop and accompanied by a number of alterations in monoaminergic signaling, although the patterns are complex across brain nuclei. In bluehead wrasses, serotonergic manipulations can decrease aggression in both laboratory and wild TP males, but no studies have closely examined the behavioral effects of manipulating monoamines during the sex change process in wrasses.

A second focus for studies of the neural mechanisms mediating behavioral sex change has been on neuropeptide hormones, especially arginine vasotocin (AVT). The first study to show differences in AVT neurons across sexual phenotypes in a sex changing fish was in the goby *T. okinawae*. In bluehead wrasse, TP males have significantly higher abundances of AVT mRNA in the preoptic area of the hypothalamus compared with females and these levels increase rapidly during experimentally induced sex change. Both the gonads and social interactions are changing as a female wrasse undergoes sex change; therefore, to tease these two factors apart, levels of AVT neurons in females changing sex with and without gonads and females that remain as subordinate females were compared. Social status affected AVT mRNA abundances, while gonadal status did not (Fig. 6). Behavioral effects of AVT also appear to depend on sexual phenotype. Neither courtship nor territorial behavior could be induced by AVT injections in females or female-mimic IP males. However, injection of AVT increases courtship in TP males and induces non-territorial TP males to establish territories. The only data available regarding neuron patterns in isotocin, a peptide closely related to oxytocin in mammals, for sex-changing species comes from blue banded gobies, where more isotocin neurons were found in females than males. Further exploration of isotocin actions in sex changing fishes would be valuable.

Summary

Our understanding of the physiological basis of sex change has increased rapidly in recent years. This is due to both technical advances in endocrine techniques and especially molecular biology as well as the identification and exploitation of powerful

model systems such as sex changing wrasses and bi-directionally sex changing gobies. Estrogen synthesis through the aromatase enzyme and the actions of the neuropeptides GnRH and AVT appear especially important in regulating sex change, but other physiological mediators are doubtless important contributors to the process. New developments such as RNA sequencing (RNAseq) are promising for future investigations of sex change. Advances in genomic methods have made it possible to employ these methods in non-model species and RNAseq has now been used to characterize changes in neural gene expression in the protandrous anemonefish *Amphiprion bicinctus* and the protogynous bluehead wrasse. The discovery of these mechanisms and development of synthetic models of the mechanistic basis of sex change from the perception of changed social environment to gonadal change should be the next stage in study of this.

Mode of Reproduction: Invertebrate Animals

Thanumalaya Subramoniam, Sathyabama University, Chennai, India

© 2018 Elsevier Inc. All rights reserved.

Introduction

Invertebrates represent the animal assemblage that lack true vertebral column. They are the most numerous kinds of living animals, having marvelled the vertebrates by their sheer diversity of form and bodily organization. Whereas the basal metazoans such as the sponges, cnidarians and flatworms are simple in organization, other invertebrate phyla, like Arthropoda, Mollusca, and Echinodermata are much more complex, usually enveloped by armour-plated exoskeletons. Most invertebrates originated and diversified in the sea, before some of them migrated to freshwater and then, species like insects, invaded terrestrial environments. Their success in the colonization of every conceivable ecological niche both in water and on land is obviously attributed to their various reproductive modes, ranging from the primitive vegetative binary fission to evolutionarily advanced sexual reproduction.

Furthermore, this diversity in reproductive strategies could be correlated to the modes of development and life history patterns, together with their ecological adaptiveness. In many invertebrates, the development is indirect with the interception of a larva, which undergoes metamorphosis to reach the adult stage. Understandably, reproductive processes are inclusive of embryonic development and larval metamorphosis in these forms. In marine invertebrates, the larvae are planktonic, playing a major role in the dispersion of species, as the adults are normally sedentary, or sessile with limited mobility. Different types of larval forms in marine invertebrates are listed in Table 1. In terrestrial and freshwater environments, however, pelagic larval development is suppressed by virtue of the production of energy-rich yolky eggs, internal fertilization and sperm storage facility in the female. Reproduction in protists is excluded in this article, as it involves mainly mitotic division of the whole body, thus differing vastly from metazoan reproduction.

Asexual Reproduction

Although sex evolved early in animal evolution, agametic cloning from somatic tissue by asexual reproductive modes is prevalent in most of the soft-bodied invertebrates such as sponges, cnidarians, flatworms, annelids, and some echinoderms, as well as urochordates, a close relative of vertebrates. In sedentary corals, asexual reproduction is the clonal propagation in which an

Table 1 Larval forms of marine invertebrates

<i>Phylum</i>	<i>Class</i>	<i>Larval forms</i>
Porifera		Parenchymula, Amphiblastula
Cnidaria	Hydrozoa	Planula, Actinula
	Scyphozoa	Planula, Actinula
	Anthozoa	Planula
Ctenophora	Tentaculata	Cydidippid
	Nuda	Cydidippid
Platyhelminthes	Turbellaria	Muller
	Cestoda	Miracidium, Cercaria
	Trematoda	Miracidium, Cercaria
	Monogenea	Onchomiracidium
Nemertea		Pilidium
Annelida	Polychaeta	Trochophore, Nectochaeta
Mollusca	Gastropoda	Trochophore
	Bivalvia	Trochophore
Lophophorates	Phoronida	Actinula
	Bryozoa	Cyphonautes
Crustacea	Copepoda	Nauplius
	Cirripedia	Nauplius, Cypris
	Malacostraca	Zoea, Megalopa (Crab); Phyllosoma, Puerulus (Lobster); Nauplius, Meta nauplius, Mysis (Shrimp)
Echinodermata	Echinoidea	Pluteus
	Asteroidea	Dipleurula, Bipinnaria, Brachiolaria
	Ophiuroidea	Ophiopluteus
	Holothuroidea	Doliolaria
Hemichordata	Enteropneusta	Tornaria
Urochordata	Tunicata	Tadpole

Table 2 Taxonomic distribution of asexual reproduction in invertebrates

	Phylum	Class	Order	Species
1. Agametic cloning				
1a. Budding	Placozoa	Trichoplacoidea	Trichoplacida	<i>Trichoplax adhaerens</i>
	Cnidaria	Anthozoa	Scleractinia	<i>Acropora palmata</i>
	Ctenophora	Tentaculata	Lobata	<i>Bolinopsis infundibulum</i>
	Xenacoelomorpha	Acoela		<i>Convolutriloba macropyga</i> <i>Convolutriloba retrogemma</i>
	Bryozoa	Phylactolaemata		<i>Lophopus crystallinus</i>
1b. Fission	Placozoa	Trichoplacoidea	Trichoplacida	<i>Trichoplax adhaerens</i>
1b. i. Binary fission (Simple)	Echinodermata	Asteroidea	Forcipulatida	<i>Allostichaster polyplex</i>
	Cnidaria	Anthozoa	Actiniaria	<i>Haliplanella lineata</i>
1b. ii. Transverse fission	Xenacoelomorpha	Acoela		<i>Convolutriloba hastifera</i> <i>Convolutriloba longifissura</i>
	Platyhelminthes	Rhabditophora		<i>Girardia tigrina</i>
1b. iii. Longitudinal fission	Annelida	Oligochaeta	Tubificida	<i>Paranais litoralis</i>
	Acoelomorpha	Acoela		<i>Paratomella unichaeta</i>
	Platyhelminthes	Rhabditophora	Tubificida	<i>Planaria fissipara</i>
1c. Fragmentation	Ctenophora	Tentaculata	Lobata	<i>Mnemiopsis leidyi</i>
	Cnidaria	Anthozoa	Actiniaria	<i>Metridium senile</i>
	Nemertea	Anopla	Heteronemertea	<i>Lineus longissimus</i>
	Xenacoelomorpha	Acoela		<i>Convolutriloba retrogemma</i>
	Hemichordata	Enteropneusta	Enteropneusta	<i>Balanoglossus capensi</i>
2. Parthenogenesis	Platyhelminthes	Trematoda	Echinostomia	<i>Philophthalmus megalurus</i>
	Rotifera	Monogononta	Ploimida	<i>Brachionus calyciflorus</i>
	Arthropoda	Crustacea	Cladocera	<i>Daphnia pulex</i>
	Arthropoda	Insecta	Hemiptera	<i>Myzus persicae</i>
			Hemiptera (Aphididea)	<i>Rhopalosiphum padi</i>

organism gives rise to the production of genetically identical replicates (ramets) by budding. Conversely, unitary animals are those that have a single body per genet (a genetic individual arising from one zygote by mitosis), which reproduce only sexually. Animals that reproduce asexually are highly regenerative, compared to obligate sexual reproducers.

In invertebrates, adult stem cells play a pivotal role in regeneration and asexual reproduction. Unlike vertebrate systems, invertebrate stem cells are not housed within a regulatory microenvironment (niche). Stem cells involved in agametic cloning in invertebrate taxa are of different kinds: choanocytes in sponges; interstitial cells in cnidarians, neoblast cells in planarians, and haemoblast stem cells in ascidians (Urochordata). Some metazoans like nematodes, rotifers, gastrotrichs and insects lack somatic stem cells and hence the inability to undergo agametic cloning. Different kinds of asexual reproduction occurring in various invertebrate animals are listed in [Table 2](#).

Gemmule Formation in Sponges

All sponges (phylum Porifera) can regenerate their bodies and reproduce asexually using totipotent stem cells. In addition, many freshwater sponges use choanocytes to develop dormant overwintering gemmules under unfavourable conditions. On return of favourable conditions, such multicellular propagules reactivate and regenerate genetically identical replicas of the original sponge.

Fission, Budding and Fragmentation

In the simplest condition, asexual reproduction can take place by subdivision of an existing body into two or more multicellular parts, followed by regeneration of the missing parts. Placozoans, the basal metazoan animals without distinct tissues or organs, reproduce exclusively by fission, whereby two parts of the animal move away from each other until their connection is ruptured ([Fig. 1](#)). In cnidarians, asexual reproduction is coupled with the sessile existence of the adult. In the freshwater hydrozoan, *Hydra*, reproduction occurs almost exclusively by budding, suppressing gamete formation ([Fig. 2](#)). In the calyx region, the parent tissue cells continuously move towards the bud-forming area and get incorporated into the growing bud. Evidently, reorientation and repolarization of parent tissue play a major role in bud formation. In addition, epithelial stem cells that mediate the morphogenetic plasticity of the tissue in regeneration may also have a similar role in asexual budding.

In *Hydra*, a new polyp bud eventually becomes a separate individual clone. However, in the coral relatives of *Hydra*, the clones do not break off, but stay attached and become a branch as in plants. Such branching colonies are also found in the bryozoan, *Membranipora*. In some anemones, the adults autotomise (self-mutilate) a tentacle, which regenerates in to a small individual. In the scyphozoan cnidarian *Aurelia*, the polypoid scyphistoma undergoes horizontal fission (strobilation) into a stack of juvenile

Fig. 1 Budding in *Hydra vulgaris*. Seen on the right side is a well grown bud and on the left, is early stage bud. Photo courtesy of Carolina Biological Supply Company.

Fig. 2 Binary fission in the placozoan, *Trichoplax*. (a) Before fission, (b)–(d) *Trichoplax* progressing through asexual reproduction by fission. Reproduced from Srivastava, M., Begovic, E., Chapman, J., *et al.*, 2008. The *Trichoplax* genome and the nature of placozoans. *Nature* 454, 955–960.

medusas, called ephyra (**Fig. 3**). The ephyra transforms into male and female medusas, which produce planula larva by sexual reproduction. The planula then settles into a sedentary scyphistoma, thus continuing the life cycle. This is termed as alternation of generation or metagenesis. Whereas asexual reproduction produces genetically identical modules that may prolong the survival of the genotype, sexual reproduction enables genetic recombination and production of new coral genotypes to enhance fitness and survival of the species.

Scyphozoans also reproduce asexually by podocyst formation, under conditions of limited food supply. Podocysts are cysts produced beneath the pedal discs of polyps of scyphozoans. They excyst small polyps that develop into active scyphistomae, which are capable of producing further podocysts as well as medusas by strobilation.

Fig. 3 Life cycle of *Aurelia* to demonstrate alternation of generation. Reproduced from Barnes, R.S.K., Calow, P., Olive, P.J.W, 1993. *The Invertebrates: A New Synthesis*, second ed. Oxford: Blackwell Science Ltd., p. 488.

In the azooxanthellate soft corals, fragmentation of the colony occurs by autotomy. New clonal colonies in the reef corals are also formed by colony fragmentation as a result of storm or wave impacts. In the anemone, longitudinal fission is the common mode of asexual reproduction, although transverse fission occurs in some forms.

Asexual reproduction in sea anemones also occurs by basal laceration, which involves regeneration from a small piece of tissue that typically includes all the three body layers. Different asexual modes of reproduction found in corals reflect the extraordinary ability of cnidarian cell lines to differentiate, dedifferentiate and redifferentiate, providing their tissues with remarkable developmental plasticity.

Budding is also common in flatworms (Platyhelminthes), which have excellent regenerative abilities. In the paratomic fission, new individuals differentiate in a chain-like fashion from a parent worm before separating from it, while in architomy, the body simultaneously fragments and only thereafter individuals differentiate from the pieces. The acoelous turbellarians release their progeny by budding from the posterior margin of the body. In the nemertean worm, belonging to genus *Lineus*, sexually immature adults undergo transverse fragmentation with subsequent regeneration. In the polychaete worm (Annelida), *Dodecaceria*, the adult worm fragments into several individual segments, each of which reconstitutes a new head and a tail by renewed segment proliferation.

Fissiparity and Budding in Echinoderms

The commonly occurring asexual mode of reproduction in sea stars and brittle stars is the division of the body across the disk, termed fissiparity. Each resulting part regenerates a complete individual which can split again. The population of the fissiparous sea star *Coscinasteria tenuispina* at Rio de Janeiro, Brazil, appears to be sustained only by fission, although these sea stars are capable of gamete production. Another asexual method is autotomy, by which a whole new animal is regenerated from a single arm or even part of an arm. Remarkably, fragmentation, fission or budding occur regularly in echinoderm larvae. Transverse fission has also been reported in the sea cucumber, *Holothuria edulis*.

Both exogenous and endogenous factors appear to be involved in regulating asexual and sexual reproduction in echinoderms. Whereas the asexual mode is related to small body size, sexual maturity is attained after an individual reaches a certain size.

Regeneration after fission is aided by existing pluripotent stem cells or de-differentiation of tissues into stem cells. Conversely, regeneration after autotomy, which takes place across predefined planes, involves the formation of an extensively proliferating blastema. However, both these regenerative processes are nerve-dependent and require neurotransmitters and neuropeptides, as growth factors.

Urochordates

The ascidian urochordates, sometimes called sea-squirts, are colonial marine invertebrates with remarkable budding capacity to form new entities from existing structures. Two types of stem cells (epithelial and blood-born) are employed in the budding of ascidians. Pallial budding (buds developed from thoracic body region) and stolonial budding (buds originating from distal tip of developing stolon) are derivatives of epithelial stem cells, whereas in vascular budding, the buds are produced by the totipotent haemoblast stem cells inside the vascular system.

Parthenogenesis

Parthenogenesis is the development of a new offspring from an unfertilized egg. Parthenogenetic lineages occur in many insect species, but are widespread among other invertebrate taxa (**Table 1**). It entails modification or absence of meiosis so that the eggs remain diploid and do not have to fuse with sperm to give rise to a diploid zygote. This kind of parthenogenesis is termed as apomictic, which produces genetically identical modules of the same genet (typical asexual reproduction). In contrast, automixis (meiotic parthenogenesis) restores diploidy by the fusion of the egg with the second polar body (e.g., free-living nematode, *Rhabditis*). Obviously, the resultant modules may not be the exact genetic replicates of the mother.

In insects, parthenogenesis may be thelytokous (female producing), arrhenotokous (male producing) or amphitokous (producing either sex). Haploid parthenogenesis is a special case in which the oocytes undergo regular meiotic division. If the eggs are fertilized, the offspring is a female, and if the eggs remain unfertilized, then parthenogenetic development results in a male offspring, which is haploid in its somatic tissues (e.g., the haplodiploid Hymenopteran insects). In social insects like the subterranean termite, *Reticuliter messperatus*, the queens produce new queens asexually by thelytokous parthenogenesis, but produce other colony members (workers and soldiers) by sexual reproduction. The parthenogenetic production of these new queens is achieved by the closing of the egg's micropyle (sperm gates) to prevent sperm entry. Yet another type, namely obligate parthenogenesis, occurs in bdelloid rotifers, in which sexual reproduction never takes place due to the lack of males in the population.

In the cladoceran rotifers and aphid insects, parthenogenesis occurs cyclically together with bouts of sexual reproduction. This is called cyclical parthenogenesis. In *Daphnia*, parthenogenetic reproduction takes place for one to several generations during favourable conditions, followed by sexual reproduction under unfavourable environments. The sexually produced long-lived dormant eggs hatch once favourable conditions return. By this alternation of generations, favourable environmental conditions can be exploited to increase the number of offspring by parthenogenetic reproduction, whereas the periodical appearance of one or more sexual generations will ensure genetic advantages such as increased heterosis, and re-assortment of genetic characters.

Sexual Reproduction

Sexual reproduction involves haploid gamete formation and their subsequent fusion (amphimixis), paving the way for genetic recombination in the newly formed genotypes to enhance fitness and survival. Over 99% of all invertebrates exhibit sexual reproduction at some stage in their lives. Sexuality has evolved early in basal metazoans like placozoans by the formation of gametic cells, even before the origin of a discrete gonad. At this level of sex cell origin, certain stem cell-like choanocytes (sponges) and interstitial cells (cnidarians) could give rise to or differentiate into both egg and sperm. In the flatworms, the gametes are loosely spread among the mesenchyme cells. Only in the coelomate invertebrates, true gonads are formed to give rise to sperm and eggs. Thus, in the majority of invertebrate animals, sexual reproduction is the main mode for the propagation of progeny.

Sexual Systems

Invertebrates have undergone dynamic species radiation, occupying diverse niches in both aquatic and terrestrial ecosystems. The correlated diversity in their morphological features and physiological adaptations has given origin to an array of sexual systems and reproductive modalities. Their highly variable patterns of reproduction have an underlying relationship with the manner in which sex determination and differentiation have taken place in different invertebrate taxa.

Although gonochorism (separate sex) is the principal mode of sexuality in invertebrates, alternative sexual systems also exist in the form of mixed-sex hermaphrodites (same sex). A hermaphrodite is an individual that produces functional male and female gametes in its lifetime. Approximately 65,000 species (about 6%) of known invertebrate animals are hermaphroditic with representation in nearly 50% of 85 invertebrate classes (**Table 3**). Unlike plants, hermaphroditism is considered to be a derived condition in invertebrate lineages. Using phylogenetic character mapping, it has been deduced that hermaphroditism is polyphyletic in invertebrate animals, having arisen from ancestral gonochorism on many separate occasions.

Hermaphroditism is rarely reported in insects, but crustaceans possess various categories of sexual systems (**Table 4**). Primitive groups of crustaceans such as notostracans and conchostracans show an extensive variation in their reproductive strategy that

Table 3 On the occurrence of hermaphroditism among invertebrate animals

Phylum	Lower taxon	Popular name	Hermaphroditism
Porifera		Sponges	Ubiquitous
Cnidaria	Hydrozoa	Hydras and hydroids	Rare
	Scyphozoa and Cubozoa	Jellyfish	Rare
	Anthozoa	Anemones and corals	Ubiquitous
Annelida	Polychaeta		Rare
	Pogonophora		Rare
	Gnathostomulida		Ubiquitous
	Oligochaeta	Earthworms, freshwater oligochaetes	Ubiquitous
	Hirudinea	Leeches	Ubiquitous
Arthropoda	Crustacea	Crabs, shrimps, crayfish, woodlice, copepods, barnacles	Rare
Tardigrada		Water bears	Rare
Sipunculida		Peanut worms	Rare
Ectoprocta		Bryozoans	Ubiquitous
Platyhelminthes	Cestoidea	Tapeworms	Ubiquitous
	Trematoda	Flukes	Ubiquitous
	Monogenea	Monogenean ectoparasites	Ubiquitous
	Turbellaria	Free-living flatworms	Ubiquitous
Nemertini		Ribbon worms	Rare
Chaetognatha		Arrow worms	Ubiquitous
Gastrotricha			Ubiquitous
Nematoda		Round worms	Present
Ctenophora		Sea walnuts, comb jellies	Ubiquitous
Phoronidea			Present
Brachiopoda		Lamp shells	Rare
Echinodermata		Starfish, brittle stars, sea urchins, sea cucumbers, sea lilies	Rare
Urochordata		Sea squirts, salps	Ubiquitous

London: Academic Press, pp. 219–248 and Avise, J., 2011. *Hermaphroditism: A Primer on the Biology, Ecology, and Evolution of Dual Sexuality*. New York, NY: Columbia University Press.

may range from gonochorism to self-fertilizing hermaphroditism and parthenogenesis. The transition from gonochorism to hermaphroditism is also evident in the clam shrimp *Eulimnadia* (Conchostraca: Crustacea) by the occurrence of an extreme sexual type, androdioecy. Interestingly, the hermaphrodites of clam shrimp lack clasping appendages for mating and thus can only self-fertilize or mate with males. In malacostracan crustaceans, androgenic gland hormone controls sex differentiation and causation of different hermaphroditic conditions.

Among the various forms of mixed sex forms, simultaneous and sequential hermaphroditism is most common. Simultaneous hermaphrodite is an animal that produces ripe sperm and ova at the same time. Although self-fertilization (selfing) is possible in many simultaneous hermaphrodites, offering fertilization assurance, many invertebrates practise cross fertilization in order to gain genetic variability among the resultant offspring. The major genetic deterrent to selfing is however inbreeding depression. Therefore, many species of simultaneously hermaphroditic invertebrates have evolved genetic self-incompatible systems that inhibit self-fertilization. Sequential or successive hermaphroditism is another form of hermaphroditism, commonly found among invertebrates like corals, molluscs and crustaceans. Here, the individual produces both male and female gametes at different periods of its life. They are either male or female at a time with a brief transitional state, called 'intersexual' during the changeover phase.

Mating Systems

Mating brings together both male and female gametes, culminating in fertilization and production of a diploid zygote. In marine invertebrates, such as cnidarians, polychaetes, and echinoderms, broadcast spawning and external fertilization is the rule, favoured by the seawater medium that could support prolonged gamete survival, fertilization and early development. For example, in the reef-building corals that live in shallow waters of the tropical oceans, both gonochoristic and hermaphroditic species release the gametes into the open sea, where random mating (fusion of gametes) occurs. The fertilized eggs undergo development to release the planktonic planula larvae, which are dispersed to far-away locations for settlement. Both external fertilization and the possession of pelagic larvae in many marine invertebrates are considered to be a primitive pattern of reproduction, with a clear advantage of colonizing new habitats. Alternatively, internal fertilization, followed by brooding of the planula larvae within their polyps also takes place in gonochoristic and simultaneously hermaphroditic anthozoan corals. The brooded larvae released from the coral polyp search for a suitable site in the reef substratum for attachment and metamorphosis into a juvenile polyp.

Table 4 Different types of sexual systems present in crustaceans

Types of sexuality	Developmental sequence	Examples
Gonochorism	Juvenile $\bar{x}$ Primary male	Brachyuran crab – <i>Scylla serrata</i>
Androdioecy	Juvenile $\bar{x}$ Primary female	
	Juvenile $\bar{x}$ Primary male	Clam Shrimp – <i>Eulimnadia texana</i>
	Juvenile $\bar{x}$ Hermaphrodites	
Sequential hermaphroditism	Juvenile $\bar{x}$ Male phase $\bar{x}$ Female phase	Humpy shrimp – <i>Pandalus goniurus</i>
a. Simple protandry	Juvenile $\bar{x}$ Male phase $\bar{x}$ Female phase	Palaemonid shrimp – <i>Processa edulis</i>
b. Protandry (with primary females)	Juvenile $\bar{x}$ Primary female	
c. Protandry (with early maturing females)	Juvenile $\rightarrow$ Male phase $\rightarrow$ Female phase “early maturing” female phase	Pink shrimp – <i>Pandalus borealis</i>
d. Protogyny	Juvenile $\bar{x}$ Female phase $\bar{x}$ Male phase	Isopod – <i>Cyathura carinata</i>
Simultaneous hermaphroditism	Juvenile $\bar{x}$ Both functional male and female in the same individual	Mud shrimp – <i>Calocaris macandreae</i>
Protandric simultaneous hermaphroditism	Juvenile $\bar{x}$ Male phase $\bar{x}$ Simultaneous hermaphrodites	Monaco Shrimp – <i>Lysmata seticaudata</i>
Intersexuality		
a. Normal intersexuals (existing as a part of life cycle)	Juvenile $\rightarrow$ Male phase $\rightarrow$ Intersexuals (Transitory) $\downarrow$ Female phase (as in protandric hermaphroditism) Juvenile $\rightarrow$ Female phase $\rightarrow$ Intersexuals (Transitory) $\downarrow$ Male phase (as in the case of protogyny)	Crayfish – <i>Parastacus varicosus</i>
	Juvenile $\bar{x}$ Male phase $\bar{x}$ Intersexuals (due to incomplete feminization by parasites)	Isopod – <i>Cyathura carinata</i>
b. Epigenetic intersexuals (arising from epigenetic factors)	Juvenile $\bar{x}$ Female phase $\bar{x}$ Intersexuals (due to androgenic gland implants)	Amphipod – <i>Gammarus deubeni</i>
c. Sex intermediates	Juvenile $\bar{x}$ Sex intermediates (hormonal disruption by methyl farnesoate)	Blue crab – <i>Calinectes sapidus</i>
d. Gynandromorphism	Embryo $\bar{x}$ Bilateral gynandromorphism (due to the chromosomal mutation in the early embryonic stage)	Cladocera – <i>Daphnia pulex</i>
	Embryo $\bar{x}$ Bilateral gynandromorphism (due to chromosomal loss during early embryonic cleavage)	Brine shrimp – <i>Artemia franciscana</i>
		Lobster – <i>Homarus gammarus</i>

Sperm Transfer Mechanisms

In terrestrial and freshwater invertebrates, release of unprotected sperm and egg into the medium is unsafe and hence fertilization must be internal, requiring direct pairing between male and female partners, often associated with complex copulatory behaviour. A feature associated with internal fertilization in invertebrate animals is the formation of sperm packets, called spermatophores, which prevent sperm loss during copulation. In the primitive insects and other cryptozoic arthropods, however, spermatophores seem to have evolved prior to the development of copulatory organs, as a means to transfer semen to effect indirect, contact-free transfer from male to female. In the more advanced insects, the spermatophores are replaced by liquid semen, transferred by well-formed penes. Spermatophores have also evolved independently in aquatic invertebrates such as crustaceans and mollusks in which they are deposited externally onto the female body or inserted into the seminal receptacles by way of copulatory organs.

Indirect sperm transfer has also been encountered in soil-dwelling polychaetes, semi terrestrial oligochaetes and leeches. In the hermaphroditic rhynchobdellid leeches, the tubular spermatophores are attached to the skin of their partners along with a hydrolytic secretion. The contraction of the spermatophore injects the sperm into the body cavity, where they reach the eggs by chemotaxis. Hypodermic insemination has also been reported in the onychophore, *Peripatus*, hermaphroditic sea slug, and some flatworms.

Mating Behaviour

Several mating behaviours have evolved in invertebrate animals in accordance with the modes of sperm transfer, the lifestyles and habitat conditions. Chemical communication by way of pheromones is also involved in the attraction of mates and the ensuing

courtship. Olfactory sex pheromones involved in the attraction of male moths over greater distances are well-known. Marine invertebrates release a water-soluble pheromone bouche to attract the opposite sex for mating and sperm transference. In the marine polychaetes, the swarming of epitokous (sexually mature) heteronereids is effected by the pheromone, inducing a nuptial dance and gamete release for external fertilization. Marine crustaceans such as the lobsters, crayfish and crabs, also use pheromones for communication and coordination of sexual activities.

Alternative Mating Strategy

Several studies have described variation in male mating behaviour among invertebrate animals. Any deviation from their common mating behaviour is considered as alternative mating strategy. In males, such deviant behaviours are associated with the assumption of reproductive phenotypes or morphotypes. Alternative mating strategy has apparently evolved in response to variation in the mating environment. The marine isopod *Paracerceis sculpta*, which breeds inside the spongocoel, has three genetically distinct male morphotypes, α male, β male, and γ male. The largest and dominant α male possesses elongated uropods and defends harems within the spongocoel. The smaller β males resemble females morphologically and invade the spongocoel by mimicking female behaviour. The γ male is tiny and adopts sneak mating tactics to gain access to females. The occurrence of dwarf males has been reported in many invertebrate species, in which they adopt several alternative mating strategies.

Types of Mating and Social Organization

Mating system refers to the procedures used in finding and securing a mate, the number of mates an individual acquires, the type of pair bonds, and the nature of parental care. The basic mating systems found in invertebrates are monogamy and polygamy. Although such mating behaviours have evolved in vertebrates to a high level, higher invertebrate groups like arthropods and molluscs practise them along with other behavioural traits such as parental care. Monogamy has been practised even among the hermaphroditic pair of a tube-dwelling polychaete worm, *Ophryotrocha diadema*, which lives together for several reproductive cycles. Mating events consist of one partner spawning eggs and the other fertilizing them. In this case of 'egg trading' both partners share brood care.

As in birds, social monogamy in certain coral-reef dwelling caridean shrimps has evolved into territorial cooperation and extended mate guarding by the male partner. In many crustaceans, mating occurs in the fresh moult stage when the female is receptive to males. Hence a new behavioural trait, namely pre-copulatory mate guarding by the males has evolved as a physiological necessity. Interestingly, in the sponge-dwelling snapping shrimp *Synalpheus*, social monogamy has given origin to advanced social systems, such as eusociality. Among other invertebrates, reproductive division of labour and cooperative care of young, resulting in eusocial condition has been well-defined only in social insects like honey bees and termite ants.

Unusual Reproductive Strategies

Polyembryony

Polyembryony, otherwise known as embryonic cloning, refers to the splitting of one sexually produced embryo into many offspring, which are genetically identical to each other but distinct from their parent(s), thus differing from asexual budding. Polyembryony occurs in a wide range of invertebrates, like cnidarians, bryozoans, insects and echinoderms (Table 5). In the cyclostome Bryozoa, cloning occurs by fission of blastula-stage embryo, with each blastomere becoming an individual offspring. In the classic example of the parasitic hymenopteran insects, the female wasp, *Copidosma*, oviposits one or two eggs inside the moth egg, which develops subsequently into a caterpillar larva. Inside the moth larva, the wasp's egg develops into a single compact mass of cells, called morula, which fragments into a large number of diminutive units that develop into two types of larvae. One type develops into a normal fertile adult, while the other type, called soldier larva, has a thin worm-like body, and becomes sterile.

Viviparity

In the great majority of invertebrate species, females lay eggs that develop and hatch in the external environment (oviparity). However, in some species females retain fertilized eggs inside the body and give birth to the young (viviparity). In the pulmonate terrestrial snails, viviparity exists in two forms: lecithotrophic viviparity (embryonic nutrition from egg yolk) and matrotrophic viviparity (nutrients supplied by maternal tissue). All species of scorpions are viviparous and the offspring are directly nourished by the mother during development. The young escape through the gonopore and crawl on to the mother's back for protection and parental care.

Insects are known to display various viviparous developments, but in a strange reproductive mode, termed hemocoelic viviparity, embryonic development occurs in the hemocoel of the mother, obtaining nutrients through their egg membrane by osmosis. In an interesting example, a parasitic female wasp injects her eggs into the ladybug. The eggs hatch and the larvae feed on the interior of the host insect. When the larva is ready to transform into a wasp, it comes out of the ladybug's abdomen and spins a cocoon, which is guarded by the ladybug from predators.

Table 5 Occurrence of polyembryony in invertebrates

Phylum	Class	Order	Species	
Cnidaria	Hydrozoa	Trachylina	<i>Pegantha</i> spp. <i>Cunina</i> spp.	
		Hydroida	<i>Cunioctantha</i> spp. <i>Polypodium hydriforme</i>	
Platyhelminthes	Monogenea	Gyrodactyloidea	<i>Gyrodactylus elegans</i>	
	Cestoidea	Eucestoda (subclass)	<i>Echinococcus</i> spp.	
Arthropoda	Trematoda	Digenea (subclass)	<i>Schistosoma</i> spp.	
	Cirripedia (Crustacea)	Rhizocephala	<i>Loxothylacus panopaei</i>	
	Insecta	Hymenoptera		
		– Encyrtidae		<i>Copidosoma</i> spp.
		– Platygastridae		<i>Platygaster</i> spp.
		– Braconidae		<i>Macrocentrus</i> spp.
– Dryinidae		<i>Macrocentrus</i> spp.		
Bryozoa	Stenolaemata	Strepsiptera	<i>Halictoxenos simplicis</i>	
		Cyclostomata	All species studied to date (e.g., <i>Crisia</i> spp.)	
Echinodermata	Asteroidea	Paxillosida	<i>Luidia</i> sp.	
	Ophiuroidea	Unidentified non-paxillosid		
		Ophiurida	<i>Ophiopluteus opulentus</i>	

Paedogenesis

In this reproductive mode, viviparity and neoteny (attainment of sexual maturity in larva) are combined. In the paedogenic insects, the ovaries of larvae become active and the eggs develop parthenogenetically. Paedogenesis often occurs in parasitoids, which live in the hemocoel of a host insect. Free-living insects (Homoptera) also exhibit paedogenesis. Here, the parthenogenetically developing larvae within the ovarioles of the mother contain embryos, so that a female aphid will contain her own grand-daughters.

Conclusion

The diversity in form and anatomical features of reproductive functions is truly reflected in the exhibition of numerous reproductive modes in invertebrate animals. The absence of phylogenetic relatedness in the occurrence of different reproductive strategies may imply their independent evolutionary origin among various invertebrate species. Nevertheless, the predominance of vegetative reproductive methods, ubiquitous or alternative to sexual propagation, furthermore indicates the co-evolution of both asexual and sexual reproductive processes in exploiting the environmental conditions. Another aspect of asexual reproduction in invertebrates is the occurrence and active participation of adult stem cells in agametic cloning of both colonial and unitary species such as the cnidarians. In *Hydra vulgaris*, induction of sexual reproduction leads to senescence and early death, whereas maintenance of asexual reproduction does not show any sign of aging. Constant self-renewal of stem cells during asexual reproduction and the loss of interstitial stem cells during gametogenesis are the proposed reasons for the above differences in their longevity. Stem cells of invertebrates demonstrate alkaline phosphatase activity (a marker of embryonic stem cells in vertebrates) and express *vasa*-like genes (as expressed in primordial germ cells), underpinning their importance in the evolution of asexual reproductive processes among various taxa. Significantly, invertebrate stem cells could become vital model systems to investigate molecular mechanisms underlying ageing and longevity in higher animals, including humans.

In invertebrates, sexual reproductive processes appear to be strongly influenced by various environmental factors. In particular, gametogenic cycles are initiated and synchronised with environmental changes by extrinsic or exogenous factors. In consequence, synchronised spawning within coral population enhanced fertilization success leading to increased planula production. For the marine invertebrates, seasonal changes in sea temperature, day length, wind or current patterns, lunar cycles or night irradiance are the major environmental factors to control reproduction and spawning. In terrestrial invertebrates like insects, a variety of extrinsic variables such as temperature, photoperiod, humidity, and food availability may influence egg production and fecundity.

The retention of primitive reproductive characteristics such as external fertilization and the development of planktonic larva in marine invertebrates demonstrate their evolutionary origin in the sea, which has changed little in physical and chemical properties since life began in it. Any change in the chemistry of seawater due to the predicted climate change could adversely affect reproduction in marine invertebrates. Conversely, terrestrialization has necessitated the development of certain modified reproductive traits such as sperm transfer via spermatophores, sperm storage in females, internal fertilization and the production of yolk-rich eggs. In spite of the widespread occurrence of sexual reproduction, invertebrates have effectively combined this mode with episodes of asexual reproduction in their complex life cycles.

Alternative Reproductive Phenotypes Within Species

Introduction: Terms and Definitions

The terms reproductive “strategy” and “tactic” originated from concepts of evolutionary game theory, but their subsequent use in the literature is muddled, with flexible definitions depending on the context of individual research studies (see [Gross \(1996\)](#), [Maynard \(1982\)](#), [Oliveira et al. \(2008\)](#), [West-Eberhard \(2003\)](#)). In game theory, a “strategy” is typically defined as a program or set of decision rules that results in specific “tactics” (or phenotypes). Traditionally, strategies and their resulting tactics implies adaptive evolved function, but ultimate benefits or whether phenotypic traits arise from genotypic or environmental factors (or a combination of both) is typically not known. The concept of “alternative reproductive tactics”, which is widespread in the literature, refers to discontinuous phenotypic traits that allow an individual sex (males or females) to obtain fertilizations in alternative ways. While these traits can be behavioural, morphological, or physiological (or some combination of these), discontinuity is easiest to observe and measure for behavioural traits. Since the adaptive value and acting selection mechanisms for individual traits is often not initially known, it may be more useful to use the term “alternative phenotypes” or “alternative pathways” when referring to modes of reproduction. Therefore, a departure from game theory to use a fitness-neutral definition accounts for situations where adaptive value is not known, as may occur in early stages of the evolution of alternative phenotypes. Thus, alternative reproductive phenotypes (ARPs) involve individuals in the same life history stage using decision rules to allocate resources to one or another trait (or suite of traits) as a means of achieving the same goal. In reproduction, these alternatives are mutually exclusive (not expressed at the same time in an individual), often result from conditional expression of different solutions to reproductive competition, exist within a sex or population at one point in time, and have obtaining fertilizations as the common end goal. While ARPs can occur in any taxa, we focus our examples and discussion on the animal kingdom. The examples presented below are by no means exhaustive, but were chosen to highlight some of the diversity of ARPs displayed across animals.

Threshold Model for Expression of Alternative Phenotypes

Reproductive alternative phenotypes can be viewed as a threshold model, with plasticity between different traits triggered by a switch (see [Emlen \(2008\)](#), [Oliveira et al. \(2008\)](#), [West-Eberhard \(2003\)](#) for discussions) ([Fig. 1](#)). Alternative phenotypes can result solely from genetics (e.g. presence of a specific allele; allelic-switch), from environmental influences (conditional-switch; polyphenism), or from a combination of both genetic and environmental factors (combined-switch). For example, genetically similar individuals can adopt specific reproductive phenotypes based on differential exposure to factors such as population density or structure, abiotic conditions, social environment, and others. Further, many animals express a certain phenotype based on conditions encountered during development. This developmental plasticity can then dictate an individuals’ phenotypic propensity as a reproducing adult. The expression of alternative phenotypes is often governed by “threshold mechanisms”, in which individuals compare some internal sensitivity threshold to their surrounding environment and then “decide” which phenotypic traits to adopt. These condition-dependent threshold mechanisms involve a switch between phenotypic alternatives, and more often result in populations with dimorphic traits rather than ones that contain intermediate phenotypes. Some argue that alternative phenotypes can only evolve when there is selection against intermediate phenotypes (disruptive selection), because if phenotypes showed continuous variation, they would not be “alternative”. However, in nature, there are many examples of systems in which some individuals in a population have intermediate phenotypes that are more sensitive to a phenotypic switch (e.g., maintain traits closer to threshold); thus, condition-dependent threshold sensitivity itself can be a substrate for evolution.

The premise of the threshold mechanism is that individuals must assess their circumstances (via external sensory inputs or internal physiology), translate it into an internal signal for change (via changes in physiology such as hormone levels, neural function, or gene expression), and then compare this signal with a specified internal threshold level. This comparison of condition-dependent internal signals and threshold then mediates whether or not the individual will switch to an alternative phenotype to achieve fertilizations. These phenotypes can also be reversible or irreversible, which often differ in their developmental timing and biological level of trait expression. For example, reversible phenotypes typically occur during the adult stage with little delay (time between environmental assessment and decisions resulting in phenotypic switch), allowing animals to quickly switch back and forth between alternatives depending on social or abiotic conditions. As such, reversible traits are most commonly behavioural (e.g., dominant aggressive vs. subordinate submissive individuals), but can also be morphological (e.g., sexual ornamentation) or physiological (e.g., hormone levels in parental vs. non-parental individuals). For example, dominant and subordinate individuals coexist in populations, with diverse examples from beetles to primates. Within a population, dominant individuals typically have higher reproductive success, but changing social interactions and resource availability can cause individuals to switch back and forth between these phenotypes; sometimes many times within their lifespan ([Fig. 2](#)). In contrast, irreversible phenotypes have a longer delay, often occur earlier in development, and can generate dramatic morphological, physiological, and behavioural alternatives that have important consequences for reproduction later in life. Irreversible switches are most common in insects, where they occur prior to or during metamorphosis (e.g. switches from larval to adult stages, as in moths and butterflies), but they also exist in other taxa (e.g., thermal rearing conditions in zebrafish results in irreversible changes in adult thermal tolerance), and can

Fig. 1 Threshold mechanism for expression of alternative reproductive phenotypes (ARP). Individuals at signal conditions below a critical threshold express one phenotype (ARP1), with its accompanying suite of morphological, physiological, and behavioural traits. Individuals at conditions above this threshold express an alternative phenotype (ARP2). The signal conditions that mediate the switch between ARPs, and its timing, varies across species, but can include factors associated with an individual's environment (abiotic or social), development, genetics, body size, hormone levels, and others.

result from phenomena such as environment, stress, hormones, or competition during certain ontogenetic stages. Importantly, each step of the threshold assessment (detection, translation, and trait expression) leading to alternative phenotypes can be a substrate for selection and evolution.

Some General Categories of Alternative Phenotypes With Examples

In the sections below, we present some of the most common examples of ARPs, within broad major categories, to highlight their diversity across animal taxa. Many ARP categorization schemes are used in the literature (e.g. based on mechanism, function, whether an ARP is reversible or irreversible, etc.), and the ones chosen below represent only one approach (see [Oliveira et al. \(2008\)](#), [Shuster and Wade \(2003\)](#), [West-Eberhard \(2003\)](#) for discussion of other schemes). It is also important to recognize that some specific examples may be applicable to multiple categories (e.g. developmental, environment, and size-dependency), as many aspects of ARPs can be linked or overlap, particularly in the early stages of discovery. Further, additional category types may also exist and will likely be required as more examples in different species are revealed in the future.

Size- and Status-Dependent Alternative Reproductive Phenotypes

Some of the most common occurrences of ARPs across all animal taxa, and their accompanying threshold switches, are related to an individual's size or status. The most prevalent examples are found in males of a species ([Fig. 2](#)). We therefore focus this section as a brief taxonomic survey of male ARPs that are related to an individual's size and status to highlight their widespread occurrence in diverse animal groups ([Oliveira et al., 2008](#)), and then discuss examples of female ARPs in a subsequent section.

ARPs associated with body size occur across all orders of insects. For example, in the horned beetle *Onthophagus binodius*, large horned males make significant investment by helping females gather provisions prior to oviposition. In contrast, small hornless males do not help females and instead search for already provisioned females, often fertilizing about half of the offspring. These smaller males have larger testes and more sperm than horned males. In other species of dung beetle, both major and minor males help females. Larger males have higher success rates with females because they win male-male contests. Smaller males attempt to copulate with females by digging into a larger males' burrow when he leaves, where they are able to move about the burrow easily (avoiding larger males in the process) and mate with females.

Fig. 2 Status-dependent male alternative reproductive phenotypes and relative reproductive success in the African cichlid fish *Pseudocrenilabrus philander*. Adoption of one of three alternative phenotypes (left) depends on relative male size and competitiveness. Territorial (T)-males aggressively defend spawning sites, perform extended courtship, and attract the majority of females, resulting in high reproductive success. Semi-T males perform aggressive opportunistic courtship and sneak spawning, with lower reproductive success. Non-T males resemble females in coloration and behaviour and use opportunistic sneak spawning that results in limited success. Individual males can reversibly switch between phenotypes. Reproductive success (shown by number of small fish at end of each arrow) is estimated from eggs spawned per spawning circumstance divided by the number of males that spawned (not genetic paternity studies). Original drawing is from Chan, T., 1987. *The role of male competition and female choice in the mating success of a lek-breeding Southern African cichlid fish Pseudocrenilabrus philander* (Pices: Cichlidae). PhD, Rhodes University, Grahamstown, South Africa. and figure is reproduced with permission from West-Eberhard, M.J., 2003. *West-Eberhard, M. J. 2003. Developmental Plasticity and Evolution*. New York: Oxford University Press.

Another classic invertebrate example of size-dependent ARPs occurs in horseshoe crabs, *Limulus polyphemus*. Small males arrive at mating beaches already clasped to females whom they spawn with, while older males arrive alone and patrol the area as satellites. Importantly, adoption of satellite behaviour is not a result of limited females, but depends on male age and size. The age or size at which individual males switch between pair-spawning and satellite behaviours may be governed by environmental conditions or female availability.

Among vertebrates, the most numerous and variable occurrences of ARPs appear in fishes. One reason for this is their indeterminate growth, which leads to large intra-sexual size dimorphism (ISD) within species. In species with large ISD, large males often employ a bourgeois tactic, monopolizing mate access and resources while smaller males are often parasitic. However, whether large ISD is a result of ARPs or vice versa is difficult to determine. Body size is the most widespread determinant of ARPs with larger males often at an advantage and smaller males sneaking to fertilize eggs. In some cases, as in cichlids and wrasses, piracy can occur when large males overtake several nests to fertilize eggs but leave other males to tend the nest. One of the most well-known size-related ARPs occurs in salmon (Fig. 3). Males can mature at 1–4 years of age and faster growing males spawn as sneaker males. Slower growing males (and all females) will migrate to sea for 1–3 years before returning to where they hatched. These slower growing anadromous males can weigh between 1–10 kg and develop a hooked lower jaw used in aggressive interactions with other males. They also court females and their success is often tied to body size. The sneaker males are significantly smaller and form their own hierarchies downstream of an anadromous male to attempt sneak spawning. Juvenile growth rate of males determines their reproductive phenotype and is influenced by genetics, parental life history, and habitat quality.

In amphibians such as frogs, most ARPs are conditional on either body size or social status, with relatively few known examples from only select species. Vocal communication is used by male frogs for mate attraction and is a mate choice determinant for females. Dominant males, or “callers”, use vocalizations to both attract females and defend territories while “satellite” males sit in silence near vocalizing males and intercept females or overtake sites occupied by caller males. Typically, males adopt either caller or satellite status for several nights, but switching within a single night has also been observed. The success rate of satellite males varies between species. For example, in *Bufo cognatus*, 95% of caller males are parasitized while only 2–14% of *Hyla picta* callers are

Fig. 3 Male Coho salmon exhibit size/status-dependent alternative reproductive phenotypes. After hatching in freshwater, all male (and female) salmon migrate to the ocean where they grow and mature. Smaller, fast-growing jack males remain at sea for approximately 6 months while larger, slow-growing males (and females) remain at sea for 1–3 years before turning to natal streams to spawn. The larger “hooknose” males develop a hooked jaw for fighting other males to facilitate spawning with females. The smaller jack males form hierarchies in freshwater where they attempt to sneak spawn with females. Growth rate of males, which has several influences, determines the males’ jack or hooknose status.

parasitized. In other species, such as *Rana clamitans*, smaller males wait for vacancies in oviposition sites rather than attempting to intercept females. In other species, smaller males may adopt satellite status as a tactic to pay off later in the breeding season. For example, satellite *Uperoleia rugosa* males often gain weight while in satellite status, increasing their chance to overtake territories of larger males later in the season. In other species, arrival time at breeding grounds may determine reproductive phenotype, rather than body size and/or condition. In *Physalaemus signifier*, for example, males that arrive early to territories vocalize to attract females and those that arrive later will not vocalize, regardless of body size and/or condition.

Social status is a common determinant of ARPs in lizards, which can be both conditional and influenced by genetics. For example, throat colour is often associated with dominance or aggression levels with lower status males employing female mimicry and/or sneaky behaviours. These approaches are often due to different endocrine pathways and/or genetics, and correlated with specific coloration (bright or cryptic colouring). In *Uta stansburiana*, sneaky males are smaller than more dominant males and exhibit traits such as yellow throat and distended abdomens that resemble those of gravid females. They will also flee from threats and are more cryptic in coloration compared to aggressive bright, dominant males. They do not hold territories, but reside near those of dominant males to sneak mating with females. These sneaky males, however, can switch to blue-throated dominant males with an increase in testosterone during the breeding season. However, only males with *by* genotype at the OBY locus can make this switch. Sneaker males with genotype *yy* are yellow-throated sneakers forever. However, only the absence of orange males (another dominant male morph) allows males to go from yellow to blue-throated.

The most well-studied ARP example in birds is that exhibited by the ruff (*Philomachus pugnax*), in which males are genetically determined to be either independents or satellites. Independent males are larger and can hold territories, while satellite males are smaller and cannot hold territories. Within the larger independent morph, males are either resident or marginal. Resident males hold a territory and marginal males do not, but try to take over those of resident males. Thus, while males are genetically fixed as satellite or independent, they can switch between resident and marginal within independent males. Satellite males make up 20% of the population, but account for only 10% of the copulations in this species.

Non-primate mammals also have a high prevalence of ARPs as a result of body size or social status. One example is seen in harem defence in which dominant males defend a harem of females. Subordinate males will adopt sneaking to attempt copulations with females when the dominant male is away or distracted. Examples of this harem defence polygyny occur in Northern and Southern elephant seals, plain zebras, and red deer. In elephant seals, smaller males that are of similar size to females will engage

in behavioural mimicry to sneak copulations. They will also wait until late in the breeding season to attempt mating when females are returning from the water and are not guarded. However the latter tactic is often unsuccessful because females have likely already mated. Territoriality based on status/size is also observed in several non-primate mammals. Dominant male bearded seals, for example, defend large aquatic territories in which they mate with females, while subordinate males roam these areas. In non-territorial mammal species, however, males will aggregate and pursue oestrous females. For example, dominant male raccoons will gather in feeding areas and tend to an individual female. Subordinate males, however, roam and encounter females away from dominant males. ARPs also exist in primates with complex social structures, and the reader is directed to the following review for examples (Setchell, 2008).

Environmental Influence on Expression of Alternative Reproductive Phenotypes

While many animals depend on abiotic cues to trigger the start of breeding season, the differences between breeding and nonbreeding (due to seasonality, environment, or cyclic reproductive cycles) animals are not considered alternative reproductive phenotypes because they occur at different points in time within the same individual. Abiotic environmental factors can, however, influence the proportion of animals within a population that are displaying each ARP at any given time. For example, female peacock wrasses mate with males that will care for their eggs. Because of this, females tend to mate with males that hold territories. A low abundance of nest availability (often due to environmental factors) causes females to mate outside the nest (low parental investment) instead of spending energy to find a suitable nest (high parental investment). This can change throughout the breeding season as nest availability changes. Similarly, different frequencies of high and low-parental investment are observed between populations inhabiting different environments.

Environmental factors can also cause more favourable conditions for certain phenotypes. For example, large and small-billed black-bellied seedcracker birds (*Pyrenestes ostrinus*) eat different types of seeds due to their different beak morphologies. Their food availability is affected by precipitation, causing them to nest at different times. Large-billed morphs nest early in the season while small-billed morphs nest late in the breeding season. Females mate randomly, independent of bill type, maintaining variation and preventing speciation. In the lizard *Urosaurus ornatus*, the environment determines whether satellite or nomadic tactics are used. Satellite males linger around other males' territories and under stressful environmental conditions, such as drought, will switch to nomadic males. However, this switch appears to be progesterone sensitivity-dependent and is therefore not solely environment-dependent.

Alternative reproductive phenotypes must occur in the same population at the same period in time. Because animals within a population are often exposed to the same environmental conditions, there are no true documented environmentally-induced ARPs in adults. However, environmental factors can have a big impact on the development of ARPs when juveniles and developing animals are exposed to them.

Developmental Influence on Expression of Alternative Reproductive Phenotypes

Conditions encountered during development can dictate an individual's reproductive phenotype as an adult. Most examples of true developmental ARPs exist in insects and are due to threshold switches that occur during development, initiating dramatic morphological, physiological, and behavioural alternatives with important consequences for adult reproduction. These can result from phenomena such as environment, stress, hormones, or competition during certain ontogenetic stages. The most common example of a developmental threshold mechanism involves hormone signals (e.g. juvenile hormone, ecdysone), where levels can be influenced by factors such as diet, temperature, and over-crowding. Hormones serve to link information from individuals' surroundings to their internal physiology during sensitive periods to initiate physiological or behavioural responses. In dung beetles (*Onthophagus* spp.), for example, juvenile hormone (JH) levels in larvae prior to metamorphosis help regulate small and large males along different developmental trajectories; large males produce horns used to guard tunnel entrances that allows them to monopolize females, while small males are hornless and adopt the alternative phenotype of sneaking into tunnels for mating opportunities (Emlen, 2008) (Fig. 4). In some species of butterflies, ecdysone (or ecdysteroid) levels during development also influence reproductive investment and life span in adults. Thus, many developmental switches operate by integrating environmental cues to phenotypic responses via hormonal (or neural) signals.

Alternative Reproductive Phenotypes in Females

Although less obvious and less frequently studied, female ARPs also exist in a variety of animals. While male ARPs are often related to access to females, females tend to use alternative phenotypes to boost their fertility or optimize the probability for success of a reproductive encounter. Female ARPs can be broadly divided into four categories (modified from Hensen and Warner (1997)): those relating to (1) parental care and investment, (2) mate choice, (3) resistance to harassment and coercion, and (4) mode of mating. Female ARPs are thought to be rarer than male ARPs, but more research is still needed, especially field studies, to determine whether they are truly less common or possibly just underreported.

Parental care and investment

The most well documented female ARP is brood parasitism. Commonly documented in fishes and birds, some females hold nests while others lay their eggs in others' nests. In the weakly electric fish *Eigenmannia virescens*, females create spawning nests in heavy

Fig. 4 Example of developmental and size-dependent alternative reproductive phenotypes in the beetle *Onthophagus taurus*. During the middle of the third larval instar of development, large and small males have different levels of juvenile hormone (JH). During a brief sensitive period before the cessation of feeding (vertical gray bar), large males have JH levels below a critical threshold (black horizontal line). Cells in the developing horns of these large individuals undergo a brief pulse of rapid proliferation during the prepupal period (blue curve), and these larvae mature into adult males with fully developed horns (inset at bottom). Small male larvae have JH concentrations above the threshold during the sensitive period, and these individuals also experience a brief pulse of ecdysone hormone (red arrow in B) resulting in only minimal proliferation of cells in the horns. Small males mature into adults with only rudimentary horns (inset at bottom). **Bottom illustration:** Female beetles dig tunnels beneath howler monkey dung, using it to provision to larvae inside. Large males with horns encounter females by 'guarding' the tunnel entrances while small males with rudimentary horns adopt a 'sneaking' approach to access females by digging side tunnels that intercept guarded tunnels below ground. Horns help guarding males block entrances from intruders, while they would hinder sneaking males by bumping against tunnel walls as they move underground. Adopted and reproduced with permission from Emlen, D.J., Hunt, J., Simmons, L.W., 2005. Evolution of sexual dimorphism and male dimorphism in the expression of beetle horns: phylogenetic evidence for modularity, evolutionary lability, and constraint. *Amer Nat.* 166 (Suppl 4) S42–68 and Emlen, D.J., 1997. Diet alters male horn allometry in the beetle *Onthophagus acuminatus* (Coleoptera: Scarabaeidae). *Proc R. Soc Lond B* 264, 567–574.

vegetation areas. Some females sneak through the plants and lay their eggs in another females' nest instead of their own, potentially driven by lack of males or inadequacy of their own spawning nest. In the mochokid catfish of Lake Tanganyika, eggs are deposited and incubated in the mouths of mouth brooding (retain developing young in their buccal cavity for the duration of development) cichlids along with the cichlid host's eggs (Fig. 5(A)). The catfish young hatch earlier and then feed on the host's developing young, exploiting both a food and refuge resource. Similarly, over 240 species of birds are known to parasitize others' nests. When females are unable to maintain their own nest, or their nest suffers from predation, they will lay their eggs in another's intact nest. The common cuckoo (*Cuculus canorus*), for example, is an obligate brood parasite. Females do not build their own nests, but instead, lay eggs that physically resemble those of the species they are parasitizing. Many bird species reject nonmimetic eggs, so cuckoo females must lay eggs in species-specific nests. This has resulted in cuckoos being divided into gentes based on the species' eggs they mimic. In the white-throated sparrow (*Zonotrichia albicollis*), both males and females have either a white or tan stripe over their eye and behaviour differences within each sex are associated with this phenotypic difference. White-striped females pursue conspecific brood parasitism and solicit copulations more often than tan-striped females.

Similar to brood parasitism, some fish species also display offspring dumping and kidnapping. Many mouth brooding cichlid fishes display parental care behaviours toward their young and, after release, will take the fully-developed offspring back into their mouth and carry them to safety. Instead of returning their young to their own nest, some fishes are observed depositing their offspring into another's nest for care. Conversely, some fishes travel to another's nest, and gather young into their mouths to care for as their own.

Mate choice and copying

Theoretical and experimental studies in fishes have demonstrated that some females mimic mate choice of others instead of making their own decisions. In guppies, this mate choice copying behaviour appears to be age-dependent. Older females are not influenced by younger females, but younger females will copy the choice of older females. Female sensory perception is often tied to reproductive state, and although not studied, could also be linked to female social status. Male katydid insects present females with resources during courtship. The females then fight with each other for the best males. In areas of high competition, females may develop larger or have increased sensitivity to male courtship songs. More research is needed to explore the plasticity in female sensory perception as it relates to ARPs.

Resistance to harassment and coercion

The most commonly observed female ARP in insects deals with the females' attempt to control male mating attempts. Some female damselflies mimic male appearance to avoid harassment, leading to lower mating but higher survival rate. Other female insects will hide from males to reduce harassment.

Some females are also more resistant to coercion than others. Male guppy fish will try to force copulation; however, females typically resist this coercion and require extensive courting. In the presence of predators, however, some females choose to forgo courtship and accept copulation without courting. Both phenotypes are present within a population, but the proportion of each depends on perceived predation risks.

Mode of mating

The most dramatic female ARPs are those between "breeding" and "nonbreeding" individuals. Some best-known examples occur in queen ants and wasps where a single queen, or sometimes multiple queens, is the sole reproducing female of the population

Fig. 5 Examples related to alternative reproductive phenotypes in females. (A) In Lake Tanganyika, the mochokid catfish will sometimes deposit their eggs with those of mouth brooding cichlids, causing the cichlid to pick them up with their own eggs and incubate them for development. The catfish young (black) develop faster and then eat the developing cichlids (gray). Reproduced with permission from Helfman, G., Collette, B.B., Facey, D.E., Bowen, B.W., 2009. *The Diversity of Fishes: Biology, Evolution, and Ecology*. Wiley-Blackwell. (B) Although variable between species, queen ants are typically the regulators of reproduction in their colonies. Due to a combination of their heredity, hormones, nutrition, development, and social environment, pupae develop into either a queen ant, male ant, or worker ant. Most queens are able to reproduce either on their own to produce more queens, or with males to produce more male or worker ants.

(Fig. 5(B)). This determination is primarily genotypic, but some research also suggests that diet at larval stages can manipulate future role. ARPs in some ant species can also be influenced by female size. For example, queen ants can choose to start a new colony or to found independent colonies using the existing colonies work force. Across ant taxa, smaller queens choose to utilize the existing work force and form dependent colonies, while larger queens found independent colonies.

Another commonly observed ARP in females is nest helpers. Some females assume the role of “breeders” while others are “helpers”. Position in this cooperative breeding can depend on several factors, including age, relatedness, and social status. In the cichlids *Neolamprologus brichardi/pulcher*, subordinate females often serve as nest helpers to breeding females. Being a helper may reduce the level of observed aggression and increase their opportunity for brood parasitism. Interestingly, the relative presence of helper females may be dependent on the abundance of available breeding substrate.

Females also display ARPs related to their mode of spawning. In the bluehead wrasse, females partake in both group- and pair-spawning. Some females mate consistently at group spawning sites, while others only spawn with a single male at pair-spawning sites. These alternative phenotypes appear to be size dependent, as nearly all females switch to pair-spawning when they reach a large size. Sneaking is another approach also observed in bluehead wrasse females. Damselfish *Chromis multilineata* females will also engage in sneaking behaviours depending on their condition. Males do not allow parasitized females into their nests. Instead, parasitized females sneak into a nest and quickly release their eggs before they are chased out. In primates, females often sneak copulate with subordinate or extra-group males, but will mate openly with dominant group males.

Yolk-provisioning strategies, egg retention, and variation in viviparity underlie most of the ARPs displayed by female reptiles. For example, female side-blotched lizards display one of two throat colours, yellow or orange, each with a different reproductive approach. Orange-throated females lay large clutches of small eggs, but yellow-throated females lay small clutches of large eggs.

Proximate Mechanisms of Alternative Reproductive Phenotypes

The initial threshold-based decisions that result in expression of ARPs require that individuals assess their surroundings. As such, knowledge of the proximate sensory, neural, and hormonal mechanisms that lead to ARPs is imperative to understand how and why ARPs develop within a species or population, and their consequences for reproductive success. Behavioural traits are more labile than morphological traits, and typically the first observable traits related to ARPs to appear; however, there are often physiological switches involved in the expression of these behaviours. For example, neural plasticity of brain circuits (e.g., synaptogenesis, excitatory/inhibitory neuron activation, neuromodulation, changes in gene expression or epigenetic factors), and changes in circulating hormones can alter reproductive behaviours in different contexts. This neural and hormonal plasticity can occur on different timescales, from rapid effects related to reversible conditional phenotypes (as in status-dependent phenotypes), to longer-term irreversible changes that occur during development or in a fixed sequence during adulthood (as in non-overlapping developmental trajectories of different reproductive male morphs in fishes like midshipman). Where ARPs are concerned, there is frequently also an uncoupling of neurobiological and gonadal traits in the expression of behavioural phenotypes. In many cases, the relative contribution of proximate mechanisms acting on multiple levels of biological organization, and whether they act independently or together to result in single or suites of alternative traits is unknown. There are numerous specific examples across animal taxa that illustrate the involvement of sensory, neural, hormonal, biochemical, epigenetic, and molecular level switches in ARP expression, and the reader is directed to the following sources: Bass and Forlano (2008), Oliveira *et al.* (2008). Understanding the proximate mechanisms that underlie ARP expression within a species can yield important insights relevant to their evolution. This includes identification of whether specific traits may have contributed to ARP trait expression or served as physiological constraints. Moving forward, it will be important to combine proximate mechanistic studies with ultimate selection and evolutionary approaches to gain a more complete understanding of the complexity of ARPs.

Evolution of Alternative Reproductive Phenotypes

The field of evolutionary biology seeks to understand mechanisms by which alternative phenotypes arise and persist in a population. While the question of how and why ARPs evolve is complex and a complete discussion is beyond the scope of this article (see Brockmann and Taborsky (2008a,b), Oliveira *et al.* (2008), Taborsky and Brockmann (2010), West-Eberhard (2003) for extensive discussions), we highlight below several of the main ways ARPs can evolve. First, the sensory systems that detect and perceive relevant changes in the environment (includes biotic and abiotic factors) can evolve. This can lead to changes in sensitivity to specific stimuli in one sensory channel, or shifts in the importance of stimuli among different sensory channels. For example, some butterfly species form pupae that match the colour of their substrates, and caterpillars can switch between alternative colours depending on sensory inputs such as photoperiod, colour of reflected light, or texture of the background substrate. Second, the physiological response mechanisms that link sensory detection to changes in physiology, such as expression changes in genes, proteins, and other signalling molecules, can evolve. These physiological changes are then revealed as alternative behaviours or morphologies if levels rise above the animal's internal switching threshold. Genetic changes in response thresholds can then alter the conditions under which alternative phenotypes are expressed. Lastly, components of the downstream signalling cascades that regulate the final condition-dependent expression of alternative traits can evolve. Importantly, each step in the process can involve a complex suite of genes that can act as substrates for evolution. However, it is also relevant to realize that phenotypic plasticity itself is a heritable trait

subject to selection and evolutionary change, and that alternative phenotypes can be viewed as a phase of evolution (West-Eberhard, 2003).

Why do alternative reproductive phenotypes evolve? ARPs are expected to exist in situations where different reproductive approaches have different benefits for acquiring fertilizations (see Fig. 2). When decision switch points for condition-dependent phenotypes are heritable and result in variable fitness, then the decision or threshold point can evolve. This becomes complicated because the decision point often relies on many variables that can vary in space and time, producing different benefits depending on environmental or social conditions. Brockmann and Taborsky (2008a,b) outline four general requirements for evolution of ARPs: (1) a mechanism by which distinct phenotypes can develop (e.g. threshold switch); (2) heritable variation in the mechanisms that control the ARPs; (3) selection that favours multiple rather than a single phenotype (e.g. disruptive selection); and (4) crossing fitness curves (points when individuals choose between alternatives with different associated trade-offs). Evolutionary processes can therefore act on underlying mechanisms, including decision rules, as well as on phenotypic flexibility (reversible or irreversible switches) or frequency within the population. Because of the higher reproductive investment in females, ARPs are expected to evolve more often in males. Moving forward, however, both sexes within a species should be taken into account to better understand the complex evolution of ARPs within individual species.

Glossary

Altricial Referring to a pattern of development in which birds are hatched at a relatively early stage of development and remain in the nest with parental care for some time.

Development All of the processes involved in the differentiation of specific tissues plus growth in body mass.

Ectotherm Animals that rely on the environment to regulate body temperature.

Endotherm Animals that internally generate heat to control body temperature.

Homeothermy Having a regulated, constant body temperature independent of changes in environmental temperature; endothermic animals use heat produced by metabolism and are homeotherms; ectotherms can also reach homeothermy through behavioral thermoregulation.

Precocial Referring to a pattern of development in which birds are hatched at a relatively advanced stage of development and are capable of leaving the nest.

Thermoregulation The regulation of constant body temperature by metabolic activities that produce or dissipate heat depending on the environmental temperatures to which the animal is exposed.

The terms altricial and precocial refer to patterns of development in which the young are hatched at a relatively early stage of development (altricial) or at a much more advanced stage of development (precocial). These terms also refer to a suite of developmental characteristics at hatch as well as to behavioral and parental care patterns. In general, altricial nestlings are still undergoing rapid tissue and organ maturation at hatching, thus altricial chicks are nest-dwelling (nidicolous) and dependent on parental care. In contrast, precocial chicks are nest-fleeing (nidifugous), i.e., they leave the nest soon after hatching or immediately after hatching, and are much more self-sufficient. Altricial development is the most common pattern of development among avian species with nearly 90% of birds hatching altricial nestlings. Although most birds can easily be categorized as either altricial or precocial, these terms represent the ends of a continuum and intermediate patterns can be subdivided into a more detailed classification. For instance, at the precocial end of the spectrum, hatchlings of very precocial species such as megapode birds are fully feathered as adults and hatchlings of some species can fly on the day they hatch out of their eggs. Examples of birds with altricial development include songbirds, pigeons, parrots, woodpeckers, and hummingbirds. Examples of precocial species include ducks, chickens, quail, grouse, and ostriches. Intermediate patterns include examples such as semiprecocial gulls and terns, which are able to leave the nest after a few days but stay in the general area, and semialtricial herons and hawks, which stay in the nest for several weeks but are capable of coordinated movements within the nest. It should be noted that mammals, like birds, also may be categorized as altricial or precocial with respect to their developmental patterns.

General Patterns of Altricial and Precocial Development

Altricial development in birds is characterized by hatching of the young at a relatively early stage of development. There is a general trend toward altricial species laying smaller eggs with lower energy content (for embryonic nourishment) and having shorter incubation periods. Thus, it appears that these species put less energy into egg production and incubation and more energy into post-hatching care of the nestlings. Altricial hatchlings typically are unfeathered or only sparsely feathered (i.e., they lack insulation), their eyes are not open, and they are incapable of coordinated body movements (Fig. 1(A)). A consequence of hatching relatively early in development is that the young are dependent on parental care and confined to the nest for some time after hatch.

The parents of altricial nestlings must provide food and protection until the nestlings are capable of flight (fledging) and of leaving the nest to assume independent life. The relative helplessness and vulnerability of altricial nestlings means they require considerable protection. These species often nest in locations that provide protection against predators, and parents may alternate

Fig. 1 General characteristics of altricial zebra finch nestling (A) and precocial wood duck duckling (B) at 1 or 2 days posthatching.

with each other in spending time on the nest and foraging for food for the young. An adult bird arriving at the nest is greeted by begging nestlings with wide-gaping mouths into which the parent regurgitates food it has captured and stored in its crop. Nestlings often have their crops greatly distended with food. Characteristically, the parents of altricial young spend most of their daylight hours supplying food to the nestlings for 1–3 weeks after the young hatch.

Precocial development in birds is characterized by hatching of the young at much more advanced stages of development than is the case for altricial birds. Precocial species generally lay larger eggs with a larger proportion of yolk and have longer incubation periods than altricial species. Thus, precocial hens have relatively higher energy use in egg production and incubation, but relatively less energy use in the care of chicks than do altricial birds. However, in some cases very mobile precocial young may require considerable attention on the part of parents, especially in cases in which predation is likely.

Precocial chicks typically look like miniature adults of the species; their body proportions and shape are generally like those of the adults (**Fig. 1(B)**). At hatching, precocial chicks typically are covered with down feathers, their eyes are open, their nervous systems are well developed, and they are capable of coordinated locomotion within minutes to hours after hatching. Precocial chicks typically begin to drink and eat within the first day after hatching. However, during hatching the yolk sac and its remaining nutrient stores are pulled into the body and are an important source of nutrition for the next several days.

Early learning of precocial chicks is facilitated by their “imprinting” to the mother. Imprinting is the process whereby a chick develops its sense of species identity by associating with its mother or another adult during a critical learning period in early post-hatching life. In precocial young that are capable of locomotion and independent feeding, this identification with the mother results

in behaviors that enhance the survival of young chicks that must learn about food sources and are vulnerable to predation or harsh environmental conditions. Thus, chicks imprinted to the mother will remain relatively close to her or other members of the same species, can follow and learn about food sources from adults, can respond to the mother's vocalizations, and will be brooded by her for protection from severe weather.

Growth and Development

Altricial nestlings typically have “distorted” body proportions and do not look like their parents. They have well-developed heads, large mouths with wide gapes, large crops, and distended abdomens due to a large visceral mass. Organ systems that must assume function during the perihatch period are the respiratory system, those of the gastrointestinal tract, and, to a lesser extent, the nervous system. The appendages of altricial nestlings are poorly developed and incapable of coordinated locomotion; their legs cannot support the body in an upright position. The wings must undergo considerable growth, maturation, and development of flight feathers before the young are capable of flight. Water content of the tissues is high until the tissues reach functional maturity and the proportion of body water (relative to dry solids) has been used as an index of the degree of maturation of both altricial and precocial young.

Precocial chicks have much more mature body development and the muscular, skeletal, and sensory/nervous systems are considerably more advanced at hatch than is the case for altricial nestlings. As in altricial young, the respiratory and gastrointestinal organs must have functional maturity from the perihatch period onward. In addition, the functional maturity of most other organ systems is also necessary for the relative independence of precocial chicks early in posthatching life.

Investigations of tissue differentiation and maturation in altricial vs precocial chicks have not shown the striking differences in key maturation events that might have been expected based on the organ system patterns described previously. For example, the beginning of cartilage to bone transition in many skeletal elements occurs at about the same developmental stage in altricial and precocial young. However, there may be differences in the extent of bone formation (ossification), with altricial nestlings having proportionately less ossification and precocial chicks having proportionately more at a given stage of posthatching development. Similar results have been found in tissues such as muscle.

The inverse relationship between tissue functional maturity and growth potential seems to be a key factor in the differences in growth of altricial and precocial species. Most avian species with altricial development have high growth rates posthatch and delayed maturation of function in many tissues. Precocial young, which have earlier maturation of many tissue functions, have slower body growth rates posthatch (Fig. 2).

Development of Temperature Regulation

The patterns of body temperature (thermoregulatory) development are strikingly different in altricial and precocial species of birds. Altricial young are hatched in an ectothermic or cold-blooded state. Although altricial nestlings are capable of detecting temperature change and some may shiver in the cold, their capacity for heat production is very limited. In addition, their insulation is often poor, so their capability for heat retention is also limited. Consequently, their body temperatures change with the temperature of the environment (except when brooded by the parents) and their metabolic rates are low. Altricial young remain ectothermic for some time (generally 1 or 2 weeks, depending on the species), then develop homeothermy (body temperature becomes constant) relatively rapidly. During their period of ectothermy, the nestlings increase in body size (which decreases their relative surface area) and they begin to grow an insulative feather covering (Fig. 2). When the ability of the nestlings to produce metabolic heat (endothermy) increases, both the relative reduction in surface area due to growth and the insulation provided by the feathers are important in

Fig. 2 Body weight patterns in altricial mourning doves (dotted line) and precocial Japanese quail (solid line) from hatching to 6 weeks of age. While Japanese quail reach sexual maturity in 6 weeks, mourning dove young do not reach sexual maturity until 13 to 14 weeks. Adult body weights of doves (●) and quail (□) are equivalent.

conserving metabolic heat for attaining homeothermy. Body temperatures begin to increase and the nestlings shiver vigorously in response to a decrease in the environmental temperature. These processes continue and typically result in the maintenance of constant body temperatures similar to those of adults by the time fledglings leave the nest.

Before altricial young can produce metabolic heat, they have some coping mechanisms for withstanding exposure to hot and cold temperatures. During exposure to hot temperatures, nestlings will gular flutter, which refers to rapid shallow “panting” that evaporates water and withdraws heat to cool the body, appears earlier than the mechanisms for dealing with cold in some altricial nestlings. Heat may potentially be of more danger to young confined to the nest than cold, since nestlings are resilient to short term decreases in body temperature.

In response to cold temperatures, altricial nestlings may huddle to reduce heat loss. Several altricial nestlings huddled in a group may develop “effective homeothermy” before each is capable of maintaining relatively constant body temperature as an isolated individual. Huddling as a group in the nest reduces heat loss, because less total surface area is exposed relative to the mass of the group than would be the case for isolated individuals. For nestlings that are in the process of developing their capacity for metabolic heat production, the reduced heat loss achieved by huddling is of considerable advantage and allows them to achieve high and stable body temperatures while in a group.

Prior to hatching, precocial chicks, which are much more mature metabolically than altricial chicks, can detect changes in incubation temperature. In response to cooling temperature, embryos can generate heat, however it is not enough to sustain egg temperature. Normally, parents brood eggs to maintain relatively constant temperatures in the nest and some precocial embryos near hatching can signal parents to warm them up. For instance, ring-billed gull embryos make distress calls when their body temperature drops below 36 °C. After hatching, thermoregulatory function matures and young begin to produce sufficient metabolic heat to regulate their body temperature well above the temperature in the environment. Precocial hatchlings further increase their metabolic rates by shivering in response to a decrease in environmental temperature. However, precocial hatchlings have limited capability to produce heat through metabolism, and the body temperatures maintained by young chicks are lower than those of adults. During the first few days to weeks posthatch, the chicks attain adult body temperatures and the range of environmental temperatures at which they can remain homeothermic is extended. Body growth (which reduces the relative surface area) and replacement of down by juvenile plumage with improved insulative qualities are both important factors in this refinement of their thermoregulatory ability. As in altricial young, huddling in groups or brooding by parents can be very important to precocial young during harsh weather conditions.

Development of Endocrine Control Systems

Hormones play important roles in the development and growth of individual tissues and of the body as a whole. Major hormones in controlling the development of individual tissues and determining the timing of developmental events are thyroxine and triiodothyronine (the hormones produced by the thyroid gland), corticosterone (a hormone produced by the adrenal glands), growth hormones, growth factors and sex steroids such as testosterone and estrogen. Of the thyroid hormones, triiodothyronine is considered to be responsible for most thyroid hormone actions. Thyroid hormones trigger differentiation (the development of individual tissue characteristics and functions) in a number of tissues and are necessary along with other hormones for general body growth. Thyroid hormones have developmental effects in all classes of vertebrate animals. In addition, in homeothermic birds and mammals, thyroid hormones are the key controllers of the high metabolic rates that are necessary for homeothermy.

The patterns of thyroid development are distinctly different in altricial and precocial birds, as might be expected by the differences in thermoregulatory development associated with the two modes of development, and given the importance of thyroid hormones in controlling metabolic heat production. In altricial embryos the thyroid gland shows little functional development during embryonic life and around hatching (the perihatch period). After hatching, the thyroid gradually increases its capability for hormone production and release, but the thyroid hormone concentrations in the blood remain low for several days. Then thyroid hormone concentrations in the blood increase and the young develop thermoregulatory responses to cooling and are able to maintain constant body temperatures (Fig. 3(a)).

In contrast to the relatively late thyroid development in altricial nestlings, the thyroid glands of precocial species attain a relatively high level of activity during the latter half of embryonic life. During the perihatch period, there are dramatic peaks of thyroid hormone concentrations in the blood and these high hormone concentrations are important in the initial thermoregulatory responses that appear at hatch. After the perihatch period, thyroid hormone concentrations in the blood decrease, then gradually increase to adult levels (Fig. 3(b)).

Corticosterone plays an important role in maintaining energy balance during stressful situations and facilitating developmental transitions. In precocial birds, corticosterone secretion from the adrenal glands increases during the latter part of the embryonic period and peaks around hatching (Fig. 4(b)). This peak in corticosterone along with thyroid hormones is thought to contribute to the initiation of the hatching process. Precocial birds can also secrete corticosterone in response to cold and hot temperatures and other stressors during the latter part of embryonic development. After hatching, corticosterone concentrations steadily drop over the course of several days and eventually reach concentrations similar to adults. In contrast, in altricial birds, circulating corticosterone levels are low early in the nestling period and the ability of the adrenal glands to secrete corticosterone gradually increases to adult-like levels by the time the nestlings fledge (Fig. 4(a)). In some species, fledglings have higher corticosterone levels than adults. It is unknown whether corticosterone also peaks around hatching in altricial birds. However, it is hypothesized that the gradual rise in corticosterone from hatching until fledging may be equivalent to a peak of corticosterone around hatching in precocial species,

Fig. 3 Patterns of plasma concentrations of thyroid hormones (T4, thyroxine (dotted lines); T3, triiodothyronine (solid lines)) in altricial and precocial birds from mid-incubation to 2 or 3 weeks posthatch. The characteristic patterns shown here are for (a) altricial doves and (b) precocial quail. For references to the data on individual species, see McNabb, F.M.A., Olson, J.M., 1996. Fig. 5 Patterns of plasma concentrations of (a) growth hormone (GH) and (b) insulin-like growth factor-1 (IGF-1) in altricial and precocial birds. The characteristic patterns shown here are for altricial starlings (dotted lines) and precocial quail (solid lines) from hatch to 4 weeks of age. For references to data on other species see McNabb, F.M.A., Scanes, C.G., Zeman, M., 1998. Endocrine control of development. In: Starck, J.M., Ricklefs, R.E. (Eds.), *Avian Growth and Development. Evolution Within the Altricial-Precocial Spectrum*. New York: Oxford University Press.

aiding in the sudden increase in energetic demands related to leaving the nest. A rise in corticosterone during development is important for maturation of many organs, such as lungs, small intestine, liver, adrenals, and kidneys. For instance, corticosterone stimulates synthesis of surfactant in the lungs, which reduces surface tension and keeps the alveoli open.

The other hormones that are most important in growth and development are growth hormone, the insulin-like growth factors (IGF-1 and IGF-2), and insulin. Growth hormone exerts its effects on overall body growth (which is important in the development of temperature regulation, as indicated above) by stimulating the liver to produce IGFs that are released into the circulation and directly trigger growth in many tissues throughout the body. Circulating concentrations of growth hormone and IGFs have similar patterns, with some shifts in the time scale, in altricial and precocial birds (Fig. 5). Thus, circulating patterns of these growth-promoting hormones do not appear to be the key controlling factors in the different tissue/organ growth patterns observed in these two developmental modes. However, circulating patterns of growth factors may not provide all the relevant information because some tissues independently produce IGFs or other growth factors which have local effects within the tissue. Although insulin and corticosteroids are known to affect some aspects of development in chicken embryos, the effects of these hormones have not been studied systematically throughout development in either precocial or altricial birds. Likewise, differences in how thyroid hormones, growth hormone, or IGFs may be involved in triggering the different functional maturation rates of organs in altricial vs precocial embryos and chicks have not been investigated. Examples of known effects of these hormones on differentiation suggest such studies are likely to aid our understanding of these developmental modes.

Male songbirds or oscines sing songs to attract mates and defend their territory. Males learn species-specific songs during a critical window of development and the sex steroid, testosterone plays an important role in song learning. First, young males must hear the songs of the same species during the sensory period. During this phase, hearing song even for a brief period every day is enough for young males to memorize the tutor's song. Because birds learn rapidly and permanently, sensory learning of song in altricial songbirds is comparable to imprinting on individuals or objects in precocial species. Males then go through a phase where they produce generic and variable sound, similar to human babies babbling. As time passes, young start to produce more structured and less variable song until stereotyped songs are crystallized. As testes grow and secrete testosterone this triggers the crystallization of songs. It is unclear what role testosterone plays in the development of vocalizations in precocial birds.

Incubation Temperature and Avian Development

A key factor in the development of both altricial and precocial embryos is incubation temperature. Incubation temperature is closely linked with the duration of incubation, whereby eggs incubated at lower temperatures take longer to hatch than eggs incubated at higher temperatures. Embryos require a fairly narrow window of temperature for proper development to take place, although species differ in their tolerance to variable incubation temperatures. While it is well known that temperature affects hatching success of eggs for both altricial and precocial birds, more recent research in non-domesticated birds indicates that incubation temperature also affects a multitude of traits in the hatchlings, including size at hatching, growth rates, hormonal profiles, immune responses,

thermoregulation, and some evidence that incubation temperature affects overwinter survival. In general, lower incubation temperatures produce individuals with reduced physiological performance relative to individuals produced at warmer temperatures. Although incubation temperature appears to affect early growth and development of both altricial and precocial species, it is unclear if the two developmental modes differ in their responsiveness to temperature. For instance, altricial species hatch with much less mature tissues than precocial species. It may be that development and maturation remains sensitive to temperature during the post-hatch period in altricial species, but not in precocial species.

Drosophila Sexual Behavior

Scott McRobert, Saint Joseph's University, Philadelphia, PA, United States

© 2018 Elsevier Inc. All rights reserved.

Glossary

Alleles Alternative forms of a gene.

Conspecific Belonging to the same species.

Copulation Duration The time during which a pair of animals spends copulating.

Copulation Frequency The number of animals that mate during a mating experiment, expressed as a percentage.

Copulation Latency The time from the onset of courtship until the initiation of copulation.

Courtship Index The amount of time a male spends performing any of the courtship behaviors, expressed as a percentage.

Dipteran A large order of insects typically called flies. The term dipteran means “two wings.”

Ecdosion In insects, the act of emerging from a pupal case.

Female Choice A sexual system in which females are the ‘choosey’ sex, typically leading to the evolution of sexual displays in males. It is thought that females inspect the displays of potential sexual partners, choosing to mate only with the fittest males.

Fixed Action Patterns (FAP's) Highly stereotyped, innate behaviors that occurs in response to a very specific environmental cue, known as a Sign Stimulus.

Fore-tarsi The front pair of legs of an insect.

Genitalia The reproductive organs.

Genotype The entire genetic constitution of an organism.

Gravid The condition of carrying fertilized eggs.

Heterozygous The condition of having two different alleles for a specific gene.

Homozygous The condition of having identical alleles for a specific gene on both homologous chromosomes.

In copula The time during which a pair of flies are physically connected during mating.

Oviposit To lay eggs.

Phenotype The observable characteristics (morphology, behavior, etc.) of an individual. Often discussed as a result of specific genetic characteristics, or genotype.

Pheromone A chemical produced by one individual that alters the behavior of another organism.

Pomace flies Members of the family Drosophilidae, which typically feed on yeasts growing on decaying vegetation.

Sex Combs A set of distinct bristles found on the fore-tarsi of males, in some *Drosophila* species.

Sex-Linked Gene Any gene located on one of the sex chromosomes (typically the X or Y).

Sex Peptide One of the proteins carried in the seminal fluid of *Drosophila melanogaster* males.

Sign Stimulus A specific cue that elicits the production of a fixed action pattern.

Sinusoidal Variation according to a sine wave.

Tephritid Flies belonging to the family Tephritidae. Known as true fruit flies because many species in this group feed on live fruit and are, thus, agricultural pests.

Wildtype Phenotypically normal individuals, as found in nature. This term is often used in contrast to mutant individuals.

Introduction

Drosophila are small dipteran flies that are well known for their use in research and in teaching laboratories, typically in genetics courses. *Drosophilids* are often referred to as fruit flies, although this term can be misleading. True “fruit flies” (typically found in the family *Tephritidae*) are herbivores that feed on live fruit that is still on the vine (see Christensen and Foote (1960)). For this reason, true fruit flies are often agriculture pests. An example of a Tephritid would be *Ceratitis capitata*, also known as the Mediterranean fruit fly, or Med Fly. By contrast, most *Drosophilids* feed exclusively on fruit that has fallen and is rotting on the ground. Because of this, most species of *drosophila* (with a few exceptions) do not pose a threat to crops, which is one of the main reasons they have become such popular experimental organisms. *Drosophila* can be shipped around the world, from laboratory to laboratory, with no fear that escapees will damage local fruit crops. However, most scientists, students, and textbooks still refer to *Drosophila* as fruit flies. Better terms for these flies would be pomace flies, or vinegar flies, addressing their predilection for rotting fruit.

Drosophilids have become one of the most powerful model organisms in the scientific world, owing largely to a number of life history characteristics. They are small, allowing huge numbers to be kept in relatively small spaces (typically small jars and vials). They have a fast life cycle, typically moving from egg to sexually mature adult in just a couple of weeks. They breed readily in

captivity and produce large numbers of offspring from a single mating. They are easy to maintain on simple, relatively inexpensive, food. And, as noted above, most species in this group do not represent a threat to agricultural crops.

For all of the reasons noted above, *Drosophila* became the model organism for early genetics studies in the laboratory of Thomas Hunt Morgan. Around 1907, Morgan collected wild *Drosophila* from bananas placed outside his lab at Columbia University, then brought these animals in and raised them in milk bottles, pilfered from doorsteps in the area. The species Morgan caught is the now-famous *Drosophila melanogaster*, which would become one of the most powerful model organisms in scientific history.

Morgan's work involved the induction of mutations in *D. melanogaster*, and resulted in the discovery of the *white* mutation (abbreviated *w*), which alters the flies natural eye color (bright red) to a remarkably distinct, white. The discovery of this mutation marks a seminal moment in the history of the field of genetics. Morgan found that crosses using flies bearing the mutant *w* allele did not follow standard Mendelian ratios. Further study determined that the *w* gene was located on the X chromosome, thus leading to differences in the inheritance pattern between males and females. This was to be the discovery of the first sex-linked mutation (Morgan, 1910).

However, it was the work of one of Morgan's students, Alfred Sturtevant, that showed just how valuable *Drosophila* would become as a model organism for the study of animal behavior. Sturtevant noted that *Drosophila* males performed a series of display behaviors in response to *Drosophila* females (Sturtevant, 1915). These behaviors would later be described in more detail (see Spieth (1952), Bastock and Manning (1955)) and would be found to be critical to mating success in this species. *Drosophila* females who seem, initially, sexually unreceptive, will eventually become receptive to males who perform the entire sequence of sexual displays in an acceptable manner.

The Sexual System in *Drosophila*

Sexual behavior in *Drosophila* is based on a phenomenon known as female choice. This system, which is found in many animal species, centers around the fact that females are the 'choosy' sex, while males mate indiscriminately with any willing member of the opposite sex. The evolutionary basis of female choice appears to be related to the overall contribution by members of each sex to the next generation. Female contribution is generally greater than that of males, and may include the production of gametes (with eggs being more metabolically costly to produce than sperm), the cost of being pregnant, or gravid, and the potential expenditures associated with parental care (for species that have parental care). All these factors lead to a system in which females actively choose the males with whom they will mate, typically following some form of expression by the males that convinces the female that this male is evolutionarily fit. Often these male 'expressions' take the form of courtship behaviors that males perform in response to potential mates.

Male Behavior

In *Drosophila melanogaster*, male courtship involves a series of distinct behaviors. These behaviors often start with orientation, in the which the male assumes a position in which he is facing the female. If the female moves, the male chases her (known as following). He will attempt to contact her with one of his fore-tarsi (front legs) in a behavior known as tapping. Tapping may provide cues to the male by allowing him to sample chemical compounds on the female's body. The male also produces one of the most critical behaviors within the sexual display by extending and vibrating a single wing (usually the wing closest to the female). Wing vibration produces the courtship song (the behavior is known as singing), which involves a series of sound pulses that interrupt a humming sound (known as 'sine song'). The time interval between the pulses (known as the inter-pulse interval, or IPI) varies in a sinusoidal pattern, which appears to be species-specific and may aid the female in knowing that she is being courted by a conspecific male. The final behavior in the repertoire of *D. melanogaster* males is licking, in which the male attempts to contact the female with his mouth parts, or proboscis (possibly picking up chemicals from her body), and attempted copulation, in which the male curls his abdomen and attempts to contact the female's genitalia with his genitalia.

In terms of the function of courtship, the courtship song, more than any other behavior, has been shown to be crucial to increasing female receptivity to copulation. Females courted by wingless males (males whose wings have been surgically removed), will not copulate, or will take a much longer time to copulate. However, when the courtship song is played through a speaker, a female will copulate with a wingless male as quickly as she would with a normal, intact male. However, the song must be the correct song for her species. In tests with *D. melanogaster* and the closely-related *D. simulans*, females mated most quickly when they heard songs that incorporated the correct IPI for their species (Kyriacou and Hall, 1982).

Female Behavior

In many *Drosophila* species, females do not perform the complex series of display behaviors seen males. Instead, their role is to elicit courtship from males through the production of aphrodisiac pheromones. These chemicals stimulate *Drosophila* males, acting as the sign stimuli that trigger the fixed-action pattern of male courtship behavior. In *Drosophila melanogaster*, mature females produce a 27-carbon aphrodisiac pheromone whose chemical name is (Z,Z)-7, 11-heptacosadiene. This compound, when applied

to a small wad of cotton, can elicit courtship from males. However, visual cues are also important for normal sexual behavior. So, while blind mutant males can court, and wildtype males can court in the dark, these situations do not produce typical sexual behavior. Males in these circumstances have difficult time tracking the females when they run away.

For the most part, in a species like *Drosophila melanogaster*, females initially move away from a courting male. In fact, the majority of female sexual behaviors are related to their initial unwillingness to mate. Unreceptive females kick at courting males, and flick their wings at them. However, once pursued, the male's song appears to cause the female to slow down and stop performing rejection behaviors. Eventually a courted female stops altogether and, when receptive, opens vaginal plates to allow the male to mate with her. It appears that in terms of copulation, females are completely in control.

In many *Drosophila* species, copulation causes dramatic changes in the biology of the female. These changes are caused by chemicals provided by the male during copulation. In *D. melanogaster* the major effects are caused by a chemical known as sex peptide, which the male delivers to the female prior to delivering sperm. Within hours of copulation the effects of this chemical can be detected in the "mated female." She stops production of the aphrodisiac pheromone, causing her to be less attractive to other males. She also undergoes changes that make her less likely to be sexually receptive if a male does court her. These effects result in the female becoming an essentially non-sexual organism and last (again, in *D. melanogaster*) for about 5 days (see [Chapman et al. \(2003\)](#)).

The evolution of compounds like sex peptide, delivered by males, to females, during copulation, are likely a result of a phenomenon known as sperm competition. Since courtship is such a costly process for the males, in terms of time and energy, it is crucial that a male protect his investment in the next generation. If a recently-mated female was to copulate with another male, she might use his sperm preferentially over the sperm of the male who originally mated with her. Therefore, a system has evolved in males to provide chemicals that reduce the chances that the females with whom they mate will re-mate again quickly. The effects of compounds, like sex peptide, act for a period of days, during which the female lays eggs fertilized by the male that provided the sex peptide along with his sperm. She may lay hundreds of eggs before the effects of sex peptide wear off. She then becomes sexually attractive, and sexually receptive, again. The negative to this entire process is that sex peptide has been shown to shorten the life of females. Thus, we may someday see the evolution of systems within the female to counteract the effects of sex peptide.

Other Species

Drosophila melanogaster has become the most well-known *Drosophila* species, owing largely to chance as this was the species collected by Thomas Hunt Morgan. However, there is no reason to believe that *D. melanogaster* is the best representative of the entire *Drosophila* family. In fact, as would be expected in any taxonomic group, significant differences exist amongst *Drosophilids* in a number of systems, including reproductive behavior.

For example, the reproductive behavior of the species *Drosophila biarmipes*, found in Southeast Asia and India, differs dramatically from that of *D. melanogaster* (see [McRobert et al., 1997](#)). *D. biarmipes* males perform many of the same courtship behaviors as *D. melanogaster*, including orientation, following, tapping, wing extension and vibration, and attempted copulation. However, in addition to that repertoire of displays, *D. biarmipes* perform a distinctive wing display behavior in which they extend both wings, tilt them to the side, and circle in front of the female. And while the function of this behavior is not known, the conjecture is that they are literally showing their wings to the female. This may be important as the males have a single, distinct, black spot on each wing. And the wing spots are sexually dimorphic in that females do not have them. Since wing spots are not found in all *Drosophilids*, it seems possible that displaying the wing spots is necessary to show the female that she is being courted by a male of her species.

What's more, the sexual behavior of *D. biarmipes* has another dramatic difference when compared to *D. melanogaster*. This involves the post-mating behavior of females. We'll recall that *D. melanogaster* females undergo a series of changes following mating, including a reduction in sex appeal (mediated by sex peptide, which shuts off production of the aphrodisiac pheromone), and reduction in sexual receptivity, that last approximately five days. Following that period of time, *D. melanogaster* females regain their sexual attractiveness and their receptivity to courting males. In *D. biarmipes*, however, while females undergo a similar set of changes following mating, including loss of attractiveness and receptivity, the restoration of normal female behavior is quite different. While attractiveness returns, *D. biarmipes* females remain unreceptive to copulation for at least 14 days post-mating. This observation suggests that *D. biarmipes* females are capable of storing, and utilizing sperm for a longer period of time than that seen in *D. melanogaster*.

Interestingly, another Asian species, *D. suzukii*, which is closely related to *D. biarmipes*, shares many characteristics of the *D. biarmipes* reproductive behavior. *D. suzukii* males, who also have a single black spot on each wing, also perform the wing-display behavior. In addition, *D. suzukii* females also lose, then quickly regain, their sex appeal following mating. But, like the situation in *D. biarmipes*, *D. suzukii* females do not regain their sexual receptivity with 14 days of mating. The interest in the reproductive behavior of *D. suzukii* stems from the fact that this species is a true fruit fly, with females ovipositing in live fruits like blueberries, strawberries and cherries. *D. suzukii* has become a destructive invasive species causing huge losses in agricultural crops (see [Cini et al. \(2012\)](#)).

The Genetics of Reproductive Behavior in *Drosophila*

Since *Drosophila* became one of the most important model organisms for the study of genetics in the 20th Century, it seems reasonable that a fair amount has been discovered about the genes affecting sexual behavior in this species (see [Sokolowski \(2001\)](#)).

As techniques to create mutations and manipulate different aspects of the genome developed, some very creative studies came about in the field of behavioral genetics. These studies were more complex than standard genetic analysis, which often involves mutagenesis (creation of mutations through the feeding of chemicals that disrupt DNA replication), and then looking for visible mutations in the offspring (things like white eyes or missing wings). In behavioral genetics, the potential mutants must go through a screening process that involves observation of the behavior of the offspring to identify alterations in normal behavior (see [Vosshall \(2007\)](#)).

A number of genes have been identified that have an impact on normal sexual behavior in *Drosophila* (see [Greenspan and Ferveur \(2000\)](#)). Not all of these genes are, however, specifically involved in sexual behavior, but rather alter aspects of the fly which affect other systems and impinge on sexual behavior. For instance, the *white* mutation, mentioned earlier, affects vision. Males expressing the *white* mutation cannot see as well as normal flies and, while they identify females and initiate courtship through olfactory cues, they have a difficult time following when the female moves away. This affects their courtship success. So, while this gene has effects on courtship, it is not specifically a 'courtship gene.'

Other genes, again, not specifically sexual genes, can affect the male courtship song and, thus, affect sexual behavior. A mutation known as *raised* (*rsd*) affects thoracic muscles and causes the wings of a fly to be held straight up. Affected individuals cannot fly, and *rsd* males cannot extend and vibrate their wings to produce the courtship song. It has been shown that *rsd* males are less successful in their courtship of wildtype (normal) females, due to their inability to sing. However, *rsd* females mate at normal rates with *rsd* males, probably indicating a form of artificial selection within laboratory cultures.

Another mutation that affects the courtship song is known as *period* (*per*). The *per* gene is involved in all rhythmic activity within the fly, almost like an internal timer. Behaviors affected by *per* include wake/sleep cycles and the timing of emergence from the pupal case (eclosion). Another behavior that appears to be rhythmic is the courtship song. The intervals at which the male produces bursts of song oscillate sinusoidally according to a species-specific rhythm. Males expressing mutant *per* phenotypes perform abnormal song. Some *per* alleles result in a faster song rhythm, some *per* alleles result in a slower song rhythm, and some *per* alleles abolish the song rhythm completely.

A true courtship gene, however, is *fruitless* (abbreviated as *fru*). This gene appears to be the central, controlling gene, for male sexual behavior in *Drosophila*. The *fru* gene produces a protein (FruM) that is expressed in neurons within the brains of *Drosophila* males, but not in the brains of females. And it is signals from these neurons that result in the series of courtship behaviors that males perform in response to females. Abnormalities in the function of the *fru* gene lead to abnormalities in sexual behavior. For instance, males who are homozygous for the *fru* mutation court other males as strongly as they court females, often resulting in long lines of males courting each other. Furthermore, when *Drosophila* females were genetically engineered to express FruM in their brains, they performed male courtship behaviors (which are never seen in normal females).

Measuring Reproductive Behavior in *Drosophila*

Within the field of Animal Behavior, *Drosophila* are ideal organisms. They will produce complex reproductive behaviors, by both males and females, under the artificial conditions provided within the laboratory. Indeed, this would be rare in species that require specific environmental factors, such as natural food sources, or seasonal changes in temperature, light, or humidity. Creating captive conditions under which these species will perform courtship and mate is almost impossible. In addition, many species are simply so intimidated by captive conditions, or by the specter of a scientist watching them, that normal courtship and mating behaviors will never be performed. But this is not the case with *Drosophila*. If a single, sexually mature male is placed into a container (practically any container!), with a sexually mature female of the same species, he will almost certainly perform the entire complicated courtship display. It is then a simple matter of observation, either by naked eye, through a microscope, or by means of video camera, for the scientist to collect data on a wide variety of parameters. And thus, the reproductive behavior of *Drosophila* has been extensively studied.

Typical courtship studies often involve collection of very young, sexually immature, flies. This is easily done by "clearing" the stock bottles of all adults, then checking the bottles within a few hours. At that point, any adults in the bottle will have enclosed from their pupal cases since the clearing, and are thus known to be young, virgin flies. The young flies are then separated by sex (in many *Drosophila* species, males are morphologically distinct from females. For example, *D. melanogaster* males are slightly smaller than females, have dark pigmentation on the tip of their abdomens, and have a set of distinct bristles, called 'sex combs,' on their fore-tarsi), and males and females housed in separate vials until testing.

Assays on *Drosophila* courtship are performed when the flies are sexually mature (for *D. melanogaster* tests are often run at 2–5 days post-eclosion). At this point a male and female can be placed into an observation chamber (almost anything that contains the flies and enables the researcher to observe them will work – a glass vial, and small plastic well with a microscope cover slip across the top, etc.) and observed. To assess the ability of the male to court (which is sometimes important to examine the effects of mutations), or the female's ability to elicit courtship, the courtship index is determined by running a timer when the male is performing any of the courtship display behaviors within a designated observation period. For flies that mate, other measures can be determined, including copulation latency (the amount of time until copulation begins), copulation duration (the amount of time the pair remain *in copula*), and copulation frequency (the percentage of couples that mate within a given period of time). By running such assays, repeatedly, a tremendous amount of information can be gained on the courtship behavior of different *Drosophila* species, or on the effects of mutations, age, and environmental parameters such as temperature, on courtship.

Behavior: Mate Choice and Sexual Selection

Introduction

Mate choice can be simply defined as any pattern of behavior shown by members of one sex that leads to preferred mating with certain members of the opposite sex. Studies of mate choice and mating behavior have focused on a wide range of organisms. In some species, such as sage grouse and peacocks, courtship displays serve a critical role in attracting potential partners. These displays lead to mating opportunities and successful reproduction. In some cases, however, the display might not be comparable to other members of their sex and the potential partner may choose another, more attractive, partner. This type of mate choice is typically known as sexual selection. It has been used to explain mate choice in male and female animals and also men's and women's particular mating strategies.

The Evolution of Sexual Selection Theory and Its Relevance to Mate Choice

Sexual selection theory was put forward by Darwin (1871). Darwin's theory of evolution by natural selection concentrated only on adaptation in the context of particular environments. Elaborate traits and dangerous courtship rituals did not fit the model of natural selection. However, he recognized that some traits might actually threaten an individual's survival and, yet, those traits persisted. He called these traits secondary sexual characters. These traits function in reproduction but they are not necessary for reproduction. Brightly colored feathers are an example of secondary sexual characteristics but ovaries and testes are primary sexual characteristics.

Darwin argued that inherited traits which helped when competing for sexual mates will increase in frequency over time, even if they compromise survival. He called the process sexual selection and argued that it was not a subcategory of natural selection because it arises from differences in mating success specifically. Sexual selection can be anything from heightened senses when searching for a mate to decorative ornaments, weapons and signals.

According to Darwin, there were two types of sexual selection: mate choice and competition for mates. Elaborate traits were the consequence of competition and also choice for particular mates. He noted that these two strategies were not mutually exclusive. He recognized that male-male competition and female choice were interrelated because mate choice by one sex usually results in competition between the members of the other sex. The competition might be physical fights or aggressive displays directed toward competitors of the same sex or through indirect competition that resulted in gaining access to fertile females before other males.

More often than not, Darwin noted, males, rather than females, spent more time on mating competition and courtship behavior. He cited dozens of examples of species where males competed harder for mates than females did. He observed male-male competition among peacocks and other birds, for example. Male-male competition is known as intra-sexual selection. In these cases, males exhibit competitive behaviors and/or display physical features. Those with a competitive advantage typically achieve greater reproductive success by gaining access as many females as possible.

In many species males compete *before* copulation. In addition to elaborate displays, traits associated with male-male competition before copulation include body size and testes size. Body size is advantageous in fights, especially when fighting is important in gaining access to females. When males grow larger than females this is known as sexual dimorphism. In monogamous species, like ourselves, there is relatively little sexual dimorphism. If there is intense sexual selection, male canines may also be very large compared to females. This is another example of sexual dimorphism. Additional examples include horns, tusks, and spurs. Males may also compete with each other by choosing and guarding a particular territory or by building an attractive nest. As mentioned above, some males may also compete for mates by exhibiting traits that represent status. Classic examples in primates include male silverback gorillas (Harcourt and Stewart, 2007) and brightly colored male mandrills (Setchell and Dixon, 2001).

Other species may compete *after* copulation. Male-male competition also includes sperm competition and larger testicles are frequently observed in multi-male social groups that have equal access to fertile females. In species where females mate with multiple males, often in succession, males may need to produce large amounts of sperm to increase their reproductive success. Some examples of primates with large testes include chimpanzees (Boesch, 2009), woolly spider monkeys (Milton, 1985) and some species of howler monkeys (Dunn *et al.*, 2015). Millions of sperm can be produced repeatedly and, therefore, there is little investment in the production of male gametes. This has important consequences for male investment in physical and behavioral traits to attract potential mates (Table 1).

In species where multiple matings occur, a male cannot be certain that a female's offspring are fathered by him. So, generally, males also spend relatively little time caring for, and investing in, their offspring. Instead, investment in traits that are attractive to females will enhance a male's mating success. Based upon decades of research, Darwin's observation that males make greater effort to attract females and they often engage in fierce male-male competition holds true. Males also compete most intensely when female parental investment greatly exceeds that of males and/or when there are many more males than females in a social group.

One other way to capture a female's attention and increase the chance of her choosing him is with "nuptial gifts." Male bowerbirds construct a so-called "love nest" to attract females for mating. When males transfer resources to females this may affect how

Table 1 The Theory of Sexual Selection predicts that females and males have different reproductive strategies due to differences in reproductive resource availability

<i>Why male-male competition & female choice?</i>		
	<i>Female gametes</i>	<i>Male gametes</i>
Number	Few	Many
Size	Large	Small
"Cost"	"Costly"	"Cheap"
Subsequent Investment	High	Low

females produce eggs, choose partners, and even select sperm to fertilize eggs. Nuptial gifts are offered by males of numerous species, particularly insects, but there remains some debate regarding the primary function of food gifts on female reproduction and offspring survival. In some cases, a nuptial-gift-type display may be seen in some human populations.

Typically, it is believed that females are the ones who choose the partner and, as a rule, females do seem "choosy" when selecting a mate. One important reason is that females invest so much in each gamete compared to males. A female's egg is large, nutrient-filled and "expensive" to produce (Table 1). Studies of birds show that bird eggs can constitute 25% or more of a female's body weight. Mammalian ova are also limited in number and are produced infrequently. In species with internal fertilization the female carries the egg after fertilization. Since males are not anatomically tied to the egg they are typically thought to be "free" from parental care. Female mammals produce the placenta, while also providing nourishment for the embryo(s). Later, females are the ones that typically provide parental care and they produce milk after birth. In many bird species the female cares for the young after they hatch. In some species, like nonhuman primates, there is a prolonged juvenile period that requires further investment from the mother. In light of these factors, it should not be surprising that females carefully select their mates to lower the chance of losing their own reproductive investment.

A variety of factors may come into play when a female chooses a mate. It is well-documented that female birds prefer more intense or more varied courtships, favoring males with larger, more brightly colored ornamentation, more extreme rates of acoustical song or a combinations of these factors. More generally, factors can be broadly divided into direct benefits that increase female fecundity or lifespan and indirect benefits that increase the quality of offspring. One example of an indirect benefit is the production of sons that will be more attractive to females in the future, ideally these sons will inherit the attractive traits from their father. This is known as Fisher's effect (Fisher, 1930).

Females may prefer certain males for many different reasons. One preference put forward in the literature is "good genes," meaning the male has attributes that predict survivorship of offspring or possessing resources. This is known as the Zahavi handicap model (Zahavi and Zahavi, 1997). In this model, females choose males with handicaps because males with handicaps must have "good genes" in order to survive, even though they possess the fitness-reducing handicap. An example of a handicap is a peacock's tail because it may reduce fitness through the process of natural selection. It has been argued that the handicap model might evolve if the female's advantage of mating with males possessing "good genes" outweighs the cost of her offspring having to carry this handicap around in the future.

For the most part, elaborate female ornamentation has been overlooked because of the prevalence of elaborate displays in males. Females are generally not expected to invest in ornamentation unless the fitness benefits of the ornament exceed those from investing the resources directly into offspring. Circumstances under which mammalian females would benefit from honestly signaling their quality are limited. Research on nonhuman primates provide equivocal support that females signal their own quality through brightly colored sexual swelling during estrous (Higham and Petersdorf, 2017). When sex roles are reversed and males provide parental care, females exhibit elaborate and colorful displays to represent honest signals of quality.

Since Darwin's time, research on sexual selection has increased exponentially. Numerous models of mate choice evolution have been suggested. In addition to the Fisher model (females prefer a trait in males and male offspring inherit the trait to attract mates in subsequent generations), there is the Bateman model (1948) that emphasizes the difference between sexes in gamete size while making the point that male fitness would be highly variable and increased with each mating but female fitness was less variable and increased minimally. A comprehensive discussion of all mate choice models is beyond the scope of this article, however when considering human mate choice there are several models to highlight. These types of models focus on the information communicated by signals. For example, there is a condition-dependent indicator model arguing that females will prefer "good genes" which are a reliable indicator of genetic quality. There is also a genetic compatibility model that suggests females choose males who complement their own genome. The Trivers model (1972) states that the greater the level of parental investment required, the more stringent the criteria that required of potential mates. Another classic model relevant to sexual selection is the "Red Queen" hypothesis (Van Valen, 1973). This suggests a sort of co-evolutionary relationship between hosts and their parasites. The expectation of the "Red Queen" model is that sexual reproduction and recombination of genetic material from parents provides their offspring with the ability to evade infection with their novel combinations of genes.

“Marketing” and Mate Choice

Darwin, and researchers that followed him have, noted that intrasexual competition and intersexual mate choice are not mutually exclusive. If one individual draws the interest of a potential mate, a decision must be made by each party whether or not the individual is a potentially suitable mate. In most cases, the male will assess the female’s value and determine whether it is worth offering a resource incentive sufficient to prevent her from mating with another, alternative, male with whom he is, or could potentially be, in competition. Contrastingly, the female will assess this offer relative to offers potentially available elsewhere in order to determine if she should accept, or reject, the male’s offer. A male’s offer to a female is assumed to come at the expense of opportunities to mate with additional females. A female’s decision to accept the offer is assumed to prevent her from capitalizing on other mating opportunities.

For sexually reproducing species, it is important for individuals to accurately evaluate the phenotypic condition and genetic quality of potential mates. Individuals should also be adapted to display their own condition and quality, frequently through investment in sexual ornaments that serve as fitness indicators or costly signals. Ever since Darwin’s work on sexual selection, the bulk of research has focused on sexually dimorphic ornaments, usually male ornaments that evolve through female choice. Nevertheless, both sexes can show conspicuous, costly ornaments and elaborate courtship behaviors. Frequently, these types of ornaments or behaviors are non-dimorphic. They are said to serve as “species recognition markers” that arise through mutual mate choice to indicate genetic quality and phenotypic condition (Miller, 1998).

Human Mate Choice and Sexual Selection

In his book *The Descent of Man, and Selection in Relation to Sex*, Darwin argued that sexual selection played a major role in the evolution of humans and in the development of human populations. He noted that men’s and women’s mating strategies were highly variable and were the result of numerous interacting contextual cues. He explained how male-male competition for access to mates would work in humans. He specifically stated that sexual selection arises from differences in reproductive success caused by competition for access to mates. He noted that men were physically larger, taller, and stronger. He suggested that more body hair and a darker complexion might be the result of male-male competition. Darwin also pointed out that men’s and woman’s bodies were very different. Women are rounder and they generally have less body hair than men. He noted that women mature earlier and develop their secondary sexual traits, such as breasts, before men. He said that most men do not develop distinct sexual characteristics, such as beards, until they are fully mature.

Surprisingly, Darwin did not discuss how or why females made particular mate choices. At the time, it appears that he, and contemporary scholars, were less interested in the issue of female choice or perhaps they believed females made choices were based solely on the outcome of male-male competitions. Darwin did note, however, that female animals exercised mate choice and sexual selection through mate choice was comparable to artificial selection by humans. Interestingly, Darwin’s ideas put females in a very powerful evolutionary role, even though this was not widely appreciated by male Victorian biologists at the time.

For the most part, research over the past few decades has focused on mate choice as the primary mechanism for human sexual selection. Like other female mammals, women invest more in offspring than men do through gestation and nursing for up to several years. Before conception, women also expend energy in the process of gamete production. These investments are similar to what has been observed for other female mammals. When considering male investment, however, men invest heavily in offspring compared with most male mammals. This is especially true in Western culture with a history of sexual monogamy, which is relatively rare in other mammals. In humans, socially monogamous individuals pair up to mate and raise offspring at least temporarily.

How Do We Choose Our Partners?

Similar to other male mammals, men are usually larger, stronger, faster, and more physically aggressive than women. Although it might not be immediately apparent, the degree of sexual dimorphism in these traits rivals that of species with obviously intense male contests. Men may seem just modestly taller, larger and stronger when compared to women. However, when female body fat is discounted, sexual dimorphism is obvious. Men are about 50% larger than women and it has been suggested that this is the result of male-male competition. Interestingly, in humans we also see a basis for female competition since men invest heavily in offspring when compared to most other male mammals.

Visual cues for intrasexual competition, and intersexual attraction, played a major role in Darwin’s discussion of sexual selection. For the animal kingdom, he cited peacock’s tails and red male mandrill faces. More recent research provides us with examples of the relative importance of features, and colors, in humans. Symmetry, or the extent to which one-half of an image is the same as the other half, provides information about development and health. If individuals develop successfully, and symmetrically, in the face of environmental pressures, this is believed to indicate genetic quality. Some research reports that male facial symmetry and perceived masculinity correlate positively. Both are said to predict underlying genetic quality. Any deviation from perfect symmetry is believed to be a sub-optimal solution to issues that potentially include inbreeding, mutation, homozygosity, nutrition and/or pathogen load. Not all studies have found a relationship between symmetry and attractiveness. Nevertheless, preference for symmetry can be associated with benefits that include providing healthy genes to offspring and/or avoiding infection from potential partners.

While symmetry is a feature relevant for male and female faces, studies of specific features of male and female faces have also been examined with reference to mate choice. In some cases women prefer both slightly feminine-looking (Perrett *et al.*, 1998) and slightly masculine-looking (DeBruine *et al.*, 2006) male faces. At this point there is no consensus on this topic. Nevertheless, it has been suggested that facial masculinity represents markers of social and physical dominance. As a consequence, faces might advertise relevant information to mates and same-sex competitors by providing valuable information about mate quality and dominance. It has also been suggested that female preference may vary throughout the reproductive period. For example, females may prefer a masculine face when ovulating and then may prefer a more feminine face to help rear the offspring.

Feminine female faces are perceived as most attractive by males. These faces would be the product of high levels of estrogen and could communicate both fertility and good health. Research suggests that females may have evolved neotenic (baby-like) faces, high-pitched voices and fatty breasts and hips as sexual ornaments to attract male investment. Studies of male preferences also reveal that males prefer an “hourglass” shaped figure, known as a low waist to hip ratio (WHR). WHR reflects the measurement of the circumference of the waist and hips. WHR has been used as an indicator or measure of health, and also the risk of developing serious health conditions in the future. While WHR preferences may vary across human populations, WHR correlates with fertility in females and indicates pubertal onset, sex, fertility, hormonal irregularities, and/or differentiates male from female.

Another way to attract, or provide cues to, potential mates relates to the olfactory system. Humans are not known for their particularly keen sense of smell but numerous studies have reported that humans have distinct odor preferences, especially with reference to “attractiveness.” These studies followed on from research reporting that rodents prefer odors from genetically different members of the opposite sex. The preferred odors came from individuals that differed with respect to genes involved in immune response (Table 2). These genes are generally known as the major histocompatibility complex (MHC). Thus far, none of the relatively few MHC human odor preference studies have been replicated and there is no clear consensus among researchers.

There have been studies of odor preferences among women on and off the contraceptive pill. In these studies, women are asked to identify their body odor preference by smelling tee shirts worn by men over consecutive nights. Ten studies have also examined the degree of MHC dissimilarity between established couples (Table 2). Few of these studies found a relationship between MHC genetics and partner choice. Perhaps this is a consequence of the MHC being so variable in urban populations and, because of this, it could be difficult to find anything other than MHC dissimilarity except when studying small, closed populations. Thus far all of this research, while potentially interesting and important for contraception and infant health, has not yet clarified the relationship between odor preference and mate choice in humans. Importantly, there are potentially serious consequences of disrupting adaptive mate preferences by the use of hormonal contraceptives. These include fertility problems due to MHC allele-sharing among couples (Ober *et al.*, 1998) and high levels of MHC homozygosity in offspring successfully conceived.

In the early 1980s, Hamilton and Zuk (1982) hypothesized that females discriminate in favor of males bearing genotypes that provide them with resistance to parasites. An important feature of this model is that females select males according to indicator traits that reveal the mate’s infection status. Research on mate choice in birds and fish demonstrate that females can indirectly determine unhealthy males by selecting brightly colored mates, but this observation doesn’t always hold up. According to the “good genes” hypothesis, women should also be attracted to men who can provide the best genes for their offspring. If women choose mates with dissimilar MHC genotypes they are likely to produce offspring with a healthy immune response and thereby increase their own fitness. Although MHC similar partners may provide other resources, MHC dissimilar mates provide better genes. Instead of selecting for arbitrarily “good” genes, the search for heterozygosity. This argument is based on numerous studies of animals that demonstrate how MHC diversity is associated with resistance to parasites and pathogens.

Most studies have found that women are “attracted to” MHC diverse and MHC dissimilar potential mates. This is explained by referring to either the “good genes” or the “Red Queen” theories of sexual selection; although these are not mutually exclusive. When considering the “good genes” hypothesis, women may be attracted to MHC heterozygous men because these men are more likely to be healthy and to transmit better genes. In the context of MHC genes, the “Red Queen” hypothesis attributes the benefit of a polymorphic MHC to producing MHC heterozygous offspring to evade parasites.

Table 2 Studies of mate preference in humans provide inconclusive support for our reliance on odors, facial appearance or an MHC genetic basis for potential partners

Trait	Studies of Human Mate Choice		
	Number of studies	Number of individuals	Preference
Odor Preference	8	529	Disassortative N=5 None N=3
Facial Preference	7	497	Assortative N=1 MHC Heterozygosity N=2 None N=4
Partner Preference	10	6582	Assortative N=1 Disassortative N=2 None N=7

How Do Our Primate Relatives Choose Their Partners?

Sexual selection typically produces ornaments in response to mate choice and armaments in response to male–male competition. Unusually among mammals, many nonhuman primates exhibit color signals that may be related to one or both processes. Some primates are noteworthy for displaying brightly colored skin. At first glance, these colorful ornaments might appear analogous to those of birds and fish, where it might be aimed at attracting the opposite sex. A number of studies of primates, however, have shown that these traits indicate social status and are like many other mammalian sexually selected traits selected primarily through male–male competition. Primates that exhibit these color-based traits include mandrills, gelada baboons, drills, and vervet monkeys (see review in [Setchell, 2015](#)).

Whether these signals are also important in female mate choice is less clear. In rhesus macaques, for example, male coloration does not correlate with social status but is used instead for female mate choice. In mandrills, male coloration is involved in both male–male competition ([Setchell et al., 2008](#)) and female mate choice ([Setchell, 2005](#)). A study of drills found evidence that male coloration is involved in communicating social status and not in attracting females beyond the consequences of dominance rank ([Marty et al., 2009](#)). For either purpose, however, coloration serves an important purpose in the context of sexual selection.

Conclusion

Darwin, and his contemporaries, and indeed more recent biologists, have collated a substantial amount of evidence to support the concept of sexual selection. These data support the fundamental truth of Darwin's hypothesis, but many questions remain. Two areas that remain underexplored is female preference and female reproductive competition. Similarly, there is much to learn about the relationship between sexual-signal honesty, genotype and environment factors.

Courtship and Mating

What Is Courtship?

Courtship can be defined as the behavior used to obtain copulation with a partner, or to maintain reproductive interactions with an existing partner. From the shimmering tail of the peacock to the chorus of frog song during the mating season, many examples exist, including the extremely elaborate bowers created by male bowerbirds and the acrobatic dance routines performed by tropical birds such as manakins. It should be noted that courtship is particularly important for terrestrial animals for whom internal fecundation is necessary as gametes cannot survive outside of water. This places an emphasis on an agreement between partners in the mating context.

The ornaments and behavioral patterns that constitute courtship for a given species may differ considerably between the male and the female. It was such differences between the sexes that inspired Darwin (1882) to propose sexual selection as an explanation for the inheritance of such traits by means of the advantage they confer when it comes to competition for reproduction. As well as competition between males for access to females, he emphasized the role of female choice among prospective male mates based on their 'love-antics'. As such, courtship can be seen as the behavior on which mate choice is based. Indeed, the degree of difference in appearance between the sexes (sexual dimorphism) is a good indication of the degree of sexual selection within a species. The complexity of courtship behavior is also often related to strength of sexual selection.

Courtship displays are particular behavioral patterns that reappear within an individual animal in the reproductive context, with different individuals of the same species exhibiting similar behavior. In one of the earliest reports on courtship in the framework of animal behavior research, Julian Huxley (1914) described the typical sequential stages of the Great Crested Grebe's (*Podiceps cristatus*) joint choreographies that occur in the time between formation of a mating pair and copulation and successful fertilization. The male and female of a pair take part in several different recurring displays, all involving set patterns of mutual behavior, including head shaking, diving, and particular body postures. Huxley was intrigued that their bouts of courtship behavior did not lead directly to copulation and therefore could not be said to play a purely excitatory role. As the birds share parental care, he inferred that these 'ceremonies' were a self-exhausting expression of emotion that served to cement the pair bond. This underlines the dual role of courtship – as well as allowing an animal to choose the best mate, it can also strengthen the bond between a monogamous pair.

It is clear that such behavior is a central part of animal communication (see Patricelli and Hebets, 2016, for a recent overview). Courtship is usually a complex trait with multiple components, often spanning different sensory modalities and including motor behavior as well as acoustic, visual, olfactory, and/or tactile components. To date, there is no agreed-upon explanation for the existence of multiple courtship traits. Multisensory signals may function as redundant signals or backup systems, or as multiple independent messages, and may mutually amplify or otherwise interact with each other. Even within a sensory modality, different parameters of the signal can carry differing information. It has recently been proposed that the sensory and cognitive properties of the animals receiving the transmitted signals might exert an influence on the evolution of elaborate courtship displays, a theory known as sensory or perceptual bias (see Ryan and Cummings, 2013, for a review).

How Is It Studied?

Historically, the advent of Ethology in the post-war period saw a flourishing of studies on courtship. The founders of the discipline, and in particular Konrad Lorenz and Niko Tinbergen, realized that courtship contains highly ritualized patterns of behavior, often derived from other behavioral contexts such as aggression. The work of behavioral endocrinologists such as Frank A. Beach, Daniel Lehrman, and John Hutchison demonstrated that courtship is under the control of gonadal hormones and is typically activated in males by the rise in testosterone levels that occurs at the beginning of the breeding season. However, these studies also revealed that courtship is a dynamic process and changes in its structure may depend on the metabolization of circulating hormones within the brain.

Behavioral biology approaches its objects of investigation from four complementary points of view, aiming to explain the adaptive function of the behavior, its underlying mechanisms, its evolution, and its development within the animal's lifetime (Tinbergen, 1963; for a general introduction see Manning and Dawkins, 2014). In this article, we review courtship and mating in relation to each of these aspects, after discussing mating systems. It is worth noting that the majority of the work into courtship has been recently conducted within the framework of behavioral ecology, which focuses on the evolution of animal behavior, although proximate mechanisms of courtship had received considerable attention in the last quarter of the 20th century.

Methodologically, courtship has been studied using many different approaches. Empirical methods range from field research in the animals' natural habitat to laboratory work with captive animals. Both typically involve observational studies or other recordings of behavior, or collection of physiological data. The data describing aspects of courtship can then be subjected to a correlation analysis with mating success (number of mates acquired) and/or reproductive success (average number of offspring per mate). As it can be extremely difficult in fieldwork to track the outcome of copulation in terms of number of young and their survival, mating

success is often used as a proxy for reproductive success. This has been shown in some avian species to be a reasonable assumption. It is also possible to manipulate aspects of the environment (e.g., blocking access to a sapling in the arena of a courting manakin), or of the animal itself (e.g., accentuating ornaments like tail length, or using hormones to alter physiological state), and to use statistical analysis to quantify the effect of the manipulation. In the laboratory, preference tests are also possible where the dependent variable is the time spent by a test animal in proximity to one of multiple, simultaneously presented possible mates.

Thanks to technological advances in video and audio equipment, it is becoming increasingly popular to use artificial stimuli to examine the effect of an experimenter-controlled courtship display on animals' behavior or physiology. Artificial stimulus material is most commonly visual or auditory, and can take the form of either a previously recorded courtship display ('playback'), a manipulated version of a recorded display, or a completely synthesized display. These approaches provide much better experimental control of the behavior presented to test animals than do experiments using a stimulus animal, as well as access to traits beyond the range physiologically possible in stimulus animals, and a reduction in the number of experimental animals needed. In some cases artificial stimuli can be used in the field (e.g., loudspeakers can be used to relay courting calls), but they are usually more amenable to laboratory work (e.g., computers can be used to show computer-animated fish displays). A major advantage of using artificial stimuli is that the range of preference can be measured in the courted sex (usually females) and compared to the range of the trait naturally occurring in the courting sex. However, the fact that audio and video equipment is optimized for human sensory systems presents a serious limitation – although they may appear identical to the human experimenter, the artificial experimental stimulus and real-world stimulus might be perceived very differently by the target animal. Robotics has also been used to good effect in field studies, for example, to investigate the influence of male responsiveness to female behavior on mating success in a bowerbird species.

Mating Systems

Any population of animals can be characterized by its general behavioral strategy in obtaining mates. Mating systems can be subdivided by the number of mates acquired (monogamous vs. polygamous), and further distinguished by the manner in which mates are obtained, the division of labor involved in parental care of the young, and whether mating partners form a pair bond. The particular mating system that occurs can be well predicted when opportunities for reproduction are considered as a resource with costs and benefits (Emlen and Oring, 1977). While it may be beneficial to engage in polygamy in order to maximize the number of offspring, the costs of monopolizing mates must be taken into account – when opportunities to mate are limited, competition will accordingly be high to access and to defend access to mates. The two most important environmental factors that determine these costs and benefits are the spatial distribution of mates (or other relevant resources such as food or habitat), and the temporal availability of mates, taking into account the time required for parental investment in offspring.

Both males and females can be polygamous, but the number of species in which a male has multiple mates whereas the female has one or just a few is preponderant. This derives from a basic difference between gametes in the two sexes: with few exceptions, males produce large numbers of small, mobile sperms whereas females produce relatively few large, non-mobile eggs. The value of a single gamete is therefore considerably different for female and males, with the consequence that females are often much more choosy about their mates. In addition, in most terrestrial vertebrates, the time required to care for the young considerably limits the temporal availability of females as sexual partners, with the result that the operational sex ratio is typically skewed towards the male.

Monogamy is the prevalent mating system in birds, possibly due to the large parental investment required of males and females in production and incubation of the eggs, and feeding and care of precocial young. The cost of neglecting a set of offspring to court and mate with an additional partner is thought to outweigh the benefit. Although extra-pair copulations are known to occur in monogamous birds, the social mating system is monogamous when considered in terms of parental investment. Fidelity has been proposed to be advantageous in birds as repeated pairings show increased physiological synchronization, leading to faster and more efficient reproduction. In addition, reduced aggression during courtship is seen between familiar partners, and the correspondingly better physical condition of the mate may help maximize survival chances of offspring.

Polygamous mating systems include variants where individual males mate with multiple females (polygyny) or vice versa (polyandry). In some of these systems, access to mates is dealt with in intrasexual competition before courtship occurs. For example, in resource defense polygyny, males compete for control of territories and defend access to females by virtue of their territorial control of food or other resources. When it comes to elaborate courtship behavior, the most interesting mating system is male dominance polygyny, in which females and resources relevant to females cannot be monopolized, and males group together during the breeding season and are visited by females who will actively choose a mate. In the lek mating system, which is a type of male dominance polygamy, female fertility is not temporally synchronized and males will gather together and perform their courtship display for the entire breeding season. Females will visit the lek and may take several days to decide upon a mate, with the decision made on the basis of the male's courtship display. Typically, one or few males will be chosen most frequently, and many males will not mate at all. After copulation, the male contribution to the offspring is complete and the female leaves and raises the young alone. Prominent examples of this mating system are bowerbirds, who create elaborate decorated staging arenas as part of their display, and manakins, who perform acrobatic dance routines in forest arenas which they clear of leaves. The advantages to the female are clear: she can efficiently access a broad pool of candidate mates. Males in larger aggregates may profit from the cumulative signal of the group being more attractive to females in general, but although lower-ranked males will encounter females, their chance of success is extremely low.

Functional Aspects of Courtship

Why does courtship exist? Some taxa display courtship (see [Table 1](#)), but those who do not can still reproduce and survive perfectly well without it. Courtship is therefore not necessary, but it has several important advantages.

As mentioned above, courtship involves the agreement of the opposite partner in the mating context. The main purpose of courtship is to ensure that there are no errors in mating: males and females can use courtship behavior to recognize and restrict reproductive interactions to conspecifics of the opposite sex in order to avoid wasting resources invested in egg and sperm production. In insects, chemical signals often function as an aid to species and sex identification. For example, in most species of fruit flies, males decide whether to continue courting after tapping candidate mates with their forelegs to acquire a pheromone sample, in order to discriminate against flies of other species or conspecifics of the incorrect sex ([Spieth, 1974](#)). Within sexually monomorphic species, which have no outward features that allow differentiation between the sexes, courtship behavior can indicate the sex of an individual. For example, Columbidae are sexually monomorphic in appearance until they engage in courtship behavior.

As well as its importance for recognizing that a partner is of same species, the communicative exchange involved in courtship has implications for the evolution of new and distinct species (speciation) as a result of assortative mating via mate choice. If differing traits (e.g., red and blue pigmentation) and corresponding differing preferences for each trait arise within a species, assortative mating of red-preferring with red animals, and blue-preferring with blue animals can lead to reproductive isolation by color and then to speciation. For example, in cichlid fishes in which nuptial colors play an important role in courtship, evidence has been found for speciation driven in part by pigmentation-associated assortative mating on the basis of divergent evolution in female color vision ([Seehausen et al., 2008](#)). Indeed, the range of possible behaviors and/or the sensory bandwidth of an organism may play a crucial role in speciation. A greater dynamic range in possible courtship traits and sensory ability results in a higher potential for signals and preferences to diverge between populations, which can then lead to reproductive isolation of a behavior-preference combination. This is mechanistically related to sensory bias and has been proposed in anurans, where mating calls are important courtship signals, and the diversity of species is found to correlate with the complexity of the anatomy of the inner ear ([Ryan, 1986](#)).

Courtship displays are also a form of advertising. They indicate that the displaying individual is ready to mate, and are an attempt to attract prospective partners. Displays can communicate such information as reproductive status, age, and health. As such, it is thought that mate choice is based on the quality of the courting animal as communicated in the display, thereby allowing the choosing animal to access the highest quality available mate. In some animals, very elaborate displays are found which include exaggerated movements that do not correspond to the normal behavioral repertoire. A well-studied example is the golden-collared manakin (*Manacus vitellinus*). These small tropical birds are polygynous (see [Section Mating Systems](#)) and males congregate during the breeding season at a regularly used location in order to display to visiting females. Each male occupies and defends a small arena, which he keeps clear of leaves and rubbish, and which provides the staging area for his energetic courtship display involving choreographed high-speed leaps and twists, wingsnaps, and vocalizations (reviewed in [Fusani et al., 2014](#)). Sexual dimorphism has been found in the skeleton, musculature and brain of these birds, suggesting that males are specialized for planning and performing their acrobatic displays, while females may have more intricate visual processing for better evaluation of courtship.

Courtship can also play an important role in the facilitation of mating by coordinating the behavior of mates in space and time ([Bastock, 1967](#)). For example, courtship displays can aid in locating a possible partner. For small, solitary insects like grasshoppers, auditory signals are particularly useful in this regard, as they can operate over longer distances than visual or chemical information. Courtship behavior can also be used to indicate or even to facilitate arrival at the location of a suitable breeding site. This is

Table 1 Taxa with courtship

<i>Invertebrates</i>	In general, courtship is not common except for advanced arthropods, and is particularly uncommon when fertilization is external
Molluscs	Courtship has been well-characterized in terrestrial gastropods (slugs, snails) and some cephalopods (cuttlefish and squid, but not many octopods)
Insects	Courtship is uncommon but examples are found in some members of all subphyla. Most widely studied: drosophila, fireflies, moths, butterflies
Arachnids	Courtship is present in many species to allow the safe delivery of the spermatophore required for internal, indirect fertilization. Spiders and scorpions are well studied. Courtship may include nuptial gift of food. Sexual cannibalism is prevalent in some species.
Crustaceans	Courtship present mainly in malacostracans including crabs, lobsters, crayfish
<i>Vertebrates</i>	Extremely common in mammals and birds
Fish	Occurrence not only limited to species with internal fertilization. Diverse courtship displays, including olfactory, visual, acoustic, and electrical signaling. Many fish species (e.g., guppies, cichlids) are important animal models for sexual selection research in part because of their courtship and ornamentation
Amphibians	Elaborate courtship is known in salamanders with internal but not external fertilization; frogs and toads typically use simple courtship comprised of mating calls
Reptiles	Internal fertilization and courtship is common and well characterized in snakes, crocodilians, lizards, and turtles
Birds	Courtship is widespread and well studied, and very varied. In most species males perform the main part of the courtship display and it can be very elaborate
Mammals	Widespread in terrestrial and marine mammals

important in some fish species in which the eggs or future young require particular environmental conditions to survive. Elements of the display may furthermore help synchronize the physiological processes of both partners (e.g., fish in which both partners must simultaneously spawn; colonial birds in which synchronous laying reduces the effect of predation) or may be directly sexually stimulating and induce the courted partner to permit mating (e.g., insects such as *Drosophila* species, where females store sperm and the timing of fertilization is therefore not important to the male's reproductive success). Also, in most species females will indicate when they are ready to copulate.

Courtship Mechanisms

During courtship, stimuli from the potential mate, from the animal itself, and from the environment interact to have an effect on behavior. This includes seasonal effects driven by day length. The role of neuroendocrine mechanisms in reproductive behavior was elucidated by early animal experiments. The often dramatic changes in courtship behavior seen after castration made it clear that gonadal hormones play a central role in the organization of such behavior. The work of [Berthold \(1849\)](#) is often cited as the 'first' experiment in behavioral endocrinology. Berthold showed that male-typical behavior of young cockerels, including crowing, disappeared with castration but could be restored by re-implantation of the testes. A plethora of studies afterwards confirmed that treatment of immature or castrated animals with gonadal hormones can, in some cases, induce or restore courtship traits. Importantly, it has also been shown that some typically male behavior patterns can be induced in females treated with testosterone (including wingsnaps in female manakins). Although the brain circuits underlying sex-specific behavior are typically organized in a permanent manner during development, in some species the control system for such behaviors is present (to some or other degree of development) in both sexes, and the introduction of the appropriate amount of required hormones into the system is sufficient to activate the behavior via the central nervous system. The influence of gonadal hormones on the brain and its organization of courtship behavior is perhaps best understood in birds, as most species in this taxon possess courtship displays that use the acoustic or visual channels and are therefore particularly suitable to human observation (see [Fusani, 2008](#), for a review).

Historically, the ring dove (*Streptopelia risoria*) was one of the most important model species for behavioral and neuroendocrinology. Males display three different behaviors during courtship: the bowing display, in which they extend the head and bow low and parallel to the ground before rising again, simultaneously emitting a coo vocalization that differs slightly between individuals; the chasing display, in which they chase after the potential mate while vocalizing; and nest solicitation (also performed by females) in which they lower the head and raise the tail while cooing and flipping the wings. The first two behaviors are induced by testosterone, while the third is estrogen-related and is controlled in males by the aromatization in the brain of gonadal testosterone into oestradiol. Perhaps most importantly, the study of courtship and mating in ring doves revealed the behavior-mediated interaction between the various endocrine processes involved, as well as the importance of environmental stimuli including day length, availability of nesting material, presence of a potential mate ([Lehrman, 1964](#)), and the role of self-stimulation of the female by her own vocalizations.

However, we still know very little about the physiological mechanisms involved in how females decide with whom to mate. As already mentioned, courtship typically involves multiple ornaments which are shown during dynamic behavioral displays. It has previously been shown that combined visual and auditory displays induce a stronger physiological response in female ring doves than only auditory information ([Friedman, 1977](#)). The direction in which a courting male is facing also makes a difference to the observing female's physiological response, which emphasizes the importance of reciprocal social interaction between the two sexes during courtship. As already mentioned, one series of mating preference models states that females have a 'sensory bias' that evolved for reasons unrelated to sexual selection, and male ornaments 'exploit' such a bias. Regarding the neural circuitry, *Drosophila* is an excellent model organism as the brain is small. *Drosophila* behaviors and genetics are well explored, and new technologies such as optogenetics are already being used to investigate causal factors.

Evolution of Courtship

The proximate mechanisms of courtship are more fully understood when viewed in an evolutionary framework that takes into account the interplay between (typically male) courtship traits and (typically female) mate choice. Sexual selection research has mostly focused on the mechanisms through which female preferences evolved ([Andersson, 1994](#)).

Developmental Aspects

How do young animals acquire the behaviors used in courtship? On the one hand, certain behaviors seem highly stereotyped and 'innate', and need only to be activated appropriately, for example, via gonadal hormones, as seen in female birds who vocalize or move like courting males when exposed to testosterone. On the other hand, such behavioral patterns are only constituent parts of the overall courtship display, which we have noted is typically multi-component and is often clearly tailored to the audience during its execution. Bird song plays an important role in courtship of many passerines, and learning of song is a central part of development. Indeed, songbirds have been an extremely important model in neurobiological studies of learning.

In some species, more elaborate courtship displays involve targeted manipulations of the environment, for example, in bowerbirds or manakins. The development of such complex courtship behaviors has not yet been studied in great depth. Interestingly, males in some passerine bird species with sex-dimorphic plumage show delayed plumage maturation, retaining their juvenile coloring (similar to females) even after they are sexually mature. This is the case in golden-collared manakins, and although juvenile male manakins have been observed visiting the lek, it is not clear whether they learn any aspect of courtship by watching performing males.

A second important aspect is learning the appropriate audience to which a courtship display should be directed. For example, some species of *Drosophila* learn to discriminate between conspecifics and heterospecifics through experience.

Finally, it is of interest whether and how animals acquire the preferences used to choose among prospective partners. Two types of acquisition have been proposed: imprinting and learning. Imprinting is a particular form of learning resulting from early exposure to the parents or other conspecifics before or closely after birth during a rather short temporal window, and is thought to lead to rigid preference. For example, Japanese quail have been shown to acquire a preference for plumage coloration of prospective mates by imprinting (Bateson, 1978). In contrast, learning in later life by means of sexual or more general social experience, and/or continued exposure to some trait, is thought to correspond to flexible preferences. Experimental comparison of virgin females to more experienced females can provide evidence for which aspects of behavior or preference might be learned, while cross-fostering experiments have been used to investigate imprinting (see Verzijden *et al.*, 2012, for a review). A third means of influence of experience on the choosing sex's decision is also possible, namely mate-choice copying or non-independent mate choice, where the chosen mate depends primarily on which mate was chosen by previous individuals. This has been found to explain courtship outcomes in some species.

Conclusions

As Margaret Bastock concluded in her book on courtship 50 years ago, “we still have much to learn about courtship. Its significance and evolutionary origins are reasonably clear but details of its mechanisms are largely unknown. Probably the relationship between it and mating behavior differs from animal to animal and the processes involved must be studied separately in each species” (Bastock, 1967, p. 194). Although we have come further in elucidating some important mechanistic aspects in some species, much work remains to be done. New methods such as optogenetics that can be used to uncover the causal contributions of neural circuits to behavior are already being applied to investigate the mechanisms underlying courtship in mice, *Drosophila*, and songbirds. Besides technical advances, there is a need for theoretical developments in the interpretation of courtship signals. This is particularly important for elaborate displays, for which simple mechanisms based on sensory properties of the courted partners appear insufficient.

Glossary

Age-limited learning Also known as sensitive-period learning. An ontogenetic pattern in which song learning is limited to the first year of life and new songs are not developed in adulthood.

Crystallization The third stage of song production in the sensorimotor phase of song learning, when birds produce a well-structured, stereotyped version of the conspecific song model to which they were exposed during the earlier memory acquisition phase.

Open-ended learning An ontogenetic pattern in which new song patterns continue to be developed beyond the first year of life, into adulthood.

Oscine A suborder of birds in the order Passeriformes, also referred to as “songbirds”.

Plastic song The second stage of song production in the sensorimotor phase of song learning. Plastic song is louder and better structured than subsong, but still variable in form.

Sensorimotor The second major phase of song learning, which involves ongoing comparison between a sensory model of song acquired during an earlier memorization phase and auditory feedback from a bird’s own production of song.

Subsong The initial stage of song production in the sensorimotor phase of song learning. Subsong is quiet, poorly structured, and very variable in form.

Template A sensory model of song acquired during the initial memory phase of song learning as a result of listening to songs produced by adult conspecific birds.

Songbird Systematics

There are about 10,000 species of living birds. Nearly 6000 species belong to the taxonomic order Passeriformes, which consists of the oscine suborder (the songbirds), and the suboscine suborder, which includes birds such as flycatchers, antbirds, and cotingas. When we speak of “songbirds,” we are referring to the oscine birds, such as finches, sparrows, and blackbirds, within this large order. The Passeriformes order is considered to be a single evolutionary lineage derived from a common ancestor (i.e., monophyletic), and the oscines and suboscines are each viewed as monophyletic lineages within the Passeriformes. There are approximately 4000 species of songbirds, essentially all of which use learned vocalizations for communication.

General Characteristics of Song Behavior

Song Structure

Songs have well-defined acoustic structures that are unique to each species. The structure of a song can be visualized using a sound spectrograph, which plots the sound frequencies against time (see [Fig. 1](#)). Song consists of different structural components. The simplest individual sounds are called song “notes.” A sequence of one or more notes that occurs together in a regular manner in song is called a song “syllable.” A series of one or more syllables that is repeated in song is referred to as a song “phrase.” A specific combination of phrases that occurs repeatedly is a song “type.”

There is great diversity among songbird taxa in the structural complexity of song behavior. In some species, such as the white-throated sparrow (*Zonotrichia albicollis*), a male produces only one simple type of song. At the other extreme, a male brown thrasher (*Toxostoma rufum*) has a repertoire of several thousand different types of songs. Most bird species have song repertoire sizes that fall between these extremes ([Beecher and Brenowitz, 2005](#); [Brenowitz and Beecher, 2005](#)).

Sex Differences in Song Production

Songbird species show extensive diversity in sex patterns of song behavior ([Ball et al., 2008](#)). At one extreme are species in which only males sing, such as the zebra finch (*Taeniopygia guttata*). At the other extreme are several tropical species in which females and males contribute equally to elaborate song duets. Between these extremes are species in which females sing, but less commonly and with less complexity than males ([Schlinger and Brenowitz, 2017](#)). In most species, song is a sexually dimorphic behavior; males sing more often and with greater complexity.

Fig. 1 Sound spectrogram of a single song produced by a male song sparrow (*Melospiza melodia*), showing a frequency vs. time representation. The simplest individual sounds in the song are *notes*. A sequence of one or more notes that occurs together in a regular manner in song is a *syllable*. A series of one or more syllables that is repeated in song is a *phrase*. The entire combination of phrases is a song *type* that is sung repeatedly. An individual male song sparrow has a *repertoire* of several different song types.

Behavioral Functions of Song

Song is important in the reproductive behavior of birds, and serves two main functions in this context (Catchpole and Slater, 2008). In many species, song is used to declare a territory from which other birds are aggressively excluded. Breeding occurs on the territory. Mating birds decreases their ability to deter intrusions by other birds. Both males and females may use song for territorial advertisement. Song may also be used by males to attract females to mate with them, as well as to stimulate the females' reproductive behavior and physiology.

Each of these functions of song may be influenced by the number of song types that a bird produces (i.e., the repertoire size). Large repertoires are more effective at deterring intrusions on a bird's territory than are small repertoires. Males with large repertoires may mate earlier in the breeding season, and/or have more mates than conspecific males with smaller repertoires. Large repertoires may also be more effective at stimulating female reproductive physiology and behavior. Female canaries (*Serinus canaria*), for example, build nests faster and lay more eggs in response to playback of a large song repertoire than they do to a small repertoire. These effects of large song repertoires on females can increase a male's reproductive success (Beecher and Brenowitz, 2005).

Song may serve other functions, in addition to territorial advertisement and mate attraction. There is often considerable individual variation in song structure, which can enable recognition of individual birds by vocal cues alone. Such individual recognition may be important for recognition of territorial neighbors, mates, kin, and members of a social group (Catchpole and Slater, 2008). Song may also play a role in maintaining dominance hierarchies in social species such as the brown-headed cowbird (*Molothrus ater*) (Kohn et al., 2013).

The rate at which birds sing may vary seasonally. In temperate zone bird species, song used in either territorial or mate-attraction contexts is produced at higher rates during the breeding season, and at lower rates or not at all outside the breeding season. In birds species residing in the tropics, song is often used for territorial defense throughout the year.

General Characteristics of Song Development

Stages of Song Learning

One of the most interesting features of song is that it is a learned behavior. Song development is characterized by distinct stages (Marler, 1997). During an initial "memory acquisition" phase, young birds acquire a sensory model of song by listening to adult conspecifics sing. Juvenile birds begin to translate this sensory memory to a motor pattern of song production at some later time, in what is referred to as the "sensorimotor" phase of song development. The sensorimotor phase consists of three stages. Initially birds produce "subsong," which is quiet, poorly structured, and very variable in form. With continued vocal practice, young birds improve their performance of song and progress to "plastic song," which is louder and better structured, but still variable in form. Eventually, song becomes "crystallized" in structure as the birds produce a stereotyped version of the sensory model to which they were exposed earlier. The specific age at which these different phases of song development occur varies considerably between species (Beecher and Brenowitz, 2005; Brenowitz and Beecher, 2005). Also, some species develop songs by improvisation, in addition to copying songs from adult conspecifics.

There is much species diversity in ontogenetic patterns of song development. At one extreme are species referred to as "age-limited" or "sensitive-period" learners, in which song learning is limited to the first year of life and new songs are not developed in adulthood. Examples of age-limited learners include the zebra finch and white-crowned sparrow (*Zonotrichia leucophrys*) (Immelmann, 1969; Marler, 1970). At the other extreme are "open-ended" learning species in which new song patterns can be developed

beyond the first year of life. Examples include the canary and European starling (*Sturnus vulgaris*) (Marler and Waser, 1977; Mountjoy and Lemon, 1995). The development of new songs by adults of open-ended species usually occurs in a restricted seasonal manner. Other species have ontogenetic patterns of song development that fall between the extremes of age-limited and open-ended learning.

Auditory Feedback is Required for Song Learning

In most species, juvenile birds must hear the song of conspecific adults if they are to develop normal song behavior. If a young bird is isolated from hearing the songs of conspecific adults, it will not develop normal song of its species. Young birds must also be able to hear themselves sing in order to develop a crystallized version of the conspecific song learned during the earlier memorization phase (Marler, 1997). If juvenile birds are deafened after the memorization phase, but before song crystallization, they will not develop normal song (Konishi, 2004). Translating the sensory memory of song to a motor program involves an ongoing comparison between a “template” of song stored during the memorization phase and auditory feedback from a bird’s own production of song: hence the description of this phase as being “sensorimotor.”

Auditory feedback may also be necessary for the maintenance of crystallized song in adults. Previously crystallized song structure can degrade within weeks to months after an adult bird is deafened. There is variation between species in the continued reliance on auditory feedback (Woolley, 2004).

Neural Control of Song Behavior

Pathways for Song Learning and Production

Song behavior in songbirds is controlled by a discrete network of interconnected nuclei in the forebrain. Two circuits that are involved in song learning and production are illustrated in Fig. 2. The motor circuit controls song production, and is also presumed to participate in the sensorimotor phase of song learning. This circuit consists of projections from the nidopallial nucleus HVC (proper name) to the robust nucleus of the arcopallium (RA) in the telencephalon. RA projects both to the dorsomedial part of the intercollicular nucleus (DM) in the midbrain (not shown in Fig. 2) and to the tracheosyringeal part of the hypoglossal motor nucleus in the brainstem (nXIIts). Motor neurons in nXIIts send their axons to the muscles of the sound-producing organ, the syrinx. The projection from RA onto the motor neurons in nXIIts is topographically organized according to the distribution of muscle groups within the syrinx. Neuronal activity in HVC and RA is synchronized with the production of sound by the syrinx (Fee et al., 2004). If nuclei in this motor pathway are inactivated, a bird is unable to produce song.

RA also projects to nucleus retroambiguus (RAm) and nucleus ambiguus (Am) in the medulla (Fig. 2). RAm contains respiratory related neurons that fire in phase with expiration. Am contains neurons that innervate the larynx. This pattern of descending projections from RA may be critical for coordination of syringeal, respiratory, and laryngeal muscle activity during song production

Fig. 2 A schematic sagittal drawing of the songbird brain showing projections of major nuclei in the song system and the distribution of steroid receptors. The descending motor pathway (black arrows) controls the production of song. The gray arrows indicate the anterior forebrain pathway that is essential for song learning. The dotted arrow indicates input to HVC from auditory regions in the nidopallium. Abbreviations: Am, nucleus ambiguus; DLM, medial portion of the dorsolateral nucleus of the medial thalamus; LMAN, lateral portion of the magnocellular nucleus of the anterior nidopallium; RA, robust nucleus of the arcopallium; RAm, nucleus retroambiguus; V, lateral ventricle; X, Area X of the medial striatum; nXIIts, tracheosyringeal part of the hypoglossal nucleus.

(Schmidt and Goller, 2016). Birds only produce song during expiration, and the larynx may filter the sound frequencies produced by the syrinx.

A second, anterior forebrain pathway is thought to be necessary for song learning and recognition (Fig. 2). This circuit consists of projections from HVC to Area X in the striatum, then to nucleus DLM in the thalamus, from DLM to the lateral portion of the magnocellular nucleus of the anterior nidopallium (LMAN), and finally to RA. LMAN neurons that project to RA also send collaterals to Area X, thus providing the potential for feedback within this pathway. The projections within this pathway are topographically organized. Inactivation of LMAN, DLM, or Area X in adults seems to have no effect on stable song, whereas the same lesions in juveniles prevent the development of normal song. This pathway continues to be important, however, in modulating song plasticity in adults induced by manipulations like deafening or denervation of the syringeal muscles. Lesions of LMAN prevent these changes (Brainard, 2008).

There are pronounced sex differences in the volume of HVC, RA, and Area X in species in which males sing more than females (Ball *et al.*, 2008). The extent of morphological sex differences in the song system of a given species is closely related to the degree to which the sexes differ in behavioral song complexity.

Auditory Responses in the Song Control Circuits

Auditory information is conveyed from field L in the nidopallium, which is the analog of the primary auditory cortex, to HVC and then to other nuclei in the song control circuits. Neurons in both the descending motor and anterior forebrain pathways show auditory responses to song stimuli, with the most pronounced selectivity to a bird's own song, and weaker responses to other conspecific songs, heterospecific songs, and artificial stimuli. This pattern of selectivity results from a bird's experience in hearing its own song. Neurons in HVC, Area X, and LMAN initially respond unselectively in young birds prior to the start of sensorimotor song learning. They become more selective as the bird proceeds through the sensorimotor stages to song crystallization. Within the anterior forebrain pathway there is a progressive increase in song selectivity as one proceeds from Area X to DLM to LMAN (Brenowitz and Woolley, 2004).

A Circuit for Song Perception and Memory

Subdivisions of the telencephalic auditory region field L also project to the caudomedial nidopallium (NCM) and the caudomesopallium (CM), which together are analogous to mammalian secondary auditory cortex. These two regions play a role in song perception and memory. There is strong induction of the immediate early gene *EGR1* in these regions in response to presentation of conspecific song, but only weak induction in response to heterospecific song or artificial sound stimuli. Neurons in NCM show stronger electrophysiological responses to playback of familiar conspecific songs. Both the ZENK induction and auditory responses in NCM decrease with repeated presentation of the same conspecific song. This decrease in responsiveness is reminiscent of habituation, and implies that neurons in NCM form a persistent memory of the stimulus song. This type of memory could be important in the context of recognizing the songs of territorial neighbors and mates (Brenowitz and Remage-Healey, 2016).

Hormone Effects

Steroid sex hormones affect song learning and production, and the juvenile development and adult plasticity of the song circuits. The pronounced effect of sex steroids on the song system is consistent with the close relationship between song behavior and reproduction.

Effects on Song Behavior

Proper timing and amount of exposure to estrogenic and androgenic hormones are necessary for normal song learning. Estrogenic and androgenic hormones may play opposing roles in song learning. Circulating estrogen concentrations are high during the memory acquisition phase of song learning in swamp sparrows (*Melospiza georgiana*), and may facilitate the plasticity of the song circuits that underlies this stage (Marler *et al.*, 1987). Testosterone, on the other hand, may terminate this plasticity. Young male birds that are castrated or treated with anti-androgenic agents can acquire sensory memories of song and progress to plastic song, but will not crystallize song unless they are treated with testosterone (Marler *et al.*, 1988). Chronic exposure of juvenile male zebra finches to testosterone severely impairs song learning (Korsia and Bottjer, 1991).

Adult song behavior is also influenced by sex steroids. Castration of adult males reduces the rate at which they sing, and treatment with exogenous steroids can reinstate song (Arnold, 1975). It appears that both androgenic and estrogenic hormones must be present for full song activation. In temperate zone birds, seasonal changes in circulating steroid levels are closely correlated with changes in the rate of song production. In some seasonally breeding species, such as the white-crowned sparrow, song continues to be produced at a lower rate after the breeding season, when circulating steroid concentrations are low (Brenowitz, 2008). In tropical songbirds, testosterone levels tend to be low throughout the year and song behavior appears to be largely independent of this hormone. These observations suggest that while circulating steroids may modulate the level of song behavior, these hormones are not required for song in all species.

Effects on the Song Control Circuits

The brain nuclei that control song are extremely sensitive to sex steroids and their metabolites (Schlinger and Brenowitz, 2017). Nuclear androgen receptors are present in the song nuclei HVC, RA, LMAN, Area X, DM, and nXlts, as well as in the muscles of the syrinx. Classical nuclear estrogen receptors are found in HVC and DM (Fig. 2).

Steroids influence the development of multiple attributes of the song system, whereas other traits appear to be under direct genetic regulation. Estrogens, and to a lesser extent androgens, stimulate masculine growth of the song system when they are injected into very young (1–3 week posthatching) female zebra finches. The primary source of estrogen synthesis that masculinizes the song system is the telencephalon rather than the gonads. Steroids induce growth of the overall volumes of HVC, RA, Area X and LMAN, stimulate increases in neuronal size and number, and alter biochemical properties and connectivity between neurons in these nuclei (Schlinger and Brenowitz, 2017).

Sex steroids also have pronounced effects on adult song control circuits. Seasonal changes in circulating testosterone levels induce plasticity in various morphological attributes of the song nuclei, including the size of the song nuclei and individual neurons, the spacing of neurons, the survival of mature neurons and the incorporation of newly generated neurons in HVC, the spontaneous electrical activity of RA neurons, and various synaptic attributes. These changes in the structure of the song nuclei are functionally related to seasonal changes in different aspects of song behavior, including song rate, stereotypy, and the development of new song patterns (Brenowitz, 1981).

Interaction with Neurotrophins

Steroids interact with brain-derived neurotrophic factor (BDNF) during development of the song system and in adult plasticity, including the addition of newborn neurons to the HVC and seasonal changes in structure and function of the song circuits (Brenowitz, 2013). Androgens, estrogens, and BDNF interact locally within HVC to influence cell proliferation and survival. The gene for BDNF has a hormone response element, and steroid/receptor complexes thereby regulate BDNF gene expression in the developing and adult song system. The trophic effect of testosterone on the addition of new neurons to HVC is mediated by BDNF activity. Steroid-BDNF interaction may also occur transsynaptically; testosterone increases the synthesis of BDNF in HVC, and BDNF protein is then released by HVC axons on to postsynaptic cells in nucleus RA where it has trophic effects on cell size and electrical activity.

Effects on Auditory Responses

Sex steroids influence activity in auditory regions in a sex-specific manner (Brenowitz and Ramage-Healey, 2016). Neurons within the auditory forebrain, including NCM, CM, and also the thalamic region IC (central nucleus of the inferior colliculus), exhibit elevated *EGR1* expression in response to song following treatment with estrogen in female but not male zebra finches. In NCM and CM this is due to decreased response to simple stimuli like tones, compared to complex stimuli like song, and this increases the selectivity for biologically relevant sounds. Similarly, estrogenic treatment increases the sensitivity and response strength of spike-timing neurons in field L to tones and conspecific songs in breeding female, but not male, white-crowned sparrows. These findings support the general idea that prolonged increases in circulating hormone levels that bring female birds into breeding condition also produce sex-specific changes in auditory responsiveness. Male song has its greatest behavioral salience for females when they are in breeding condition, and estrogens are a seasonal internal cue that provides an effective way of enhancing auditory function at that critical time of year.

Introduction

Communication is universal among all living organisms. From single cells to the most complex of plant and animal societies, information exchange is crucial for coordinating aggregation, food source location, avoidance of harm, and, maybe most importantly, reproduction. Broadly defined, communication is the exchange of information between individuals, usually a sender and a receiver (Bradbury and Vehrencamp, 2011). In general, the pathway between a sender and a receiver is defined as a channel (Greenfield, 2002). In animals, many different types of information are exchanged in various ways: The sender's current status (e.g., aggressive, dominant, or subordinate) can be conveyed, as well as the sender's affiliation to a certain sex, species, or group. Accurate information transfer in a reproductive context is pivotal for finding, attracting, securing, and eventually reproducing with suitable mates (Saetre *et al.*, 1997; Maan and Seehausen, 2011). Concerning insects, by far the most diverse group of animals (Chapman, 2009), communication has the difficult distinction of often being beyond our own human perception or even imagination (Greenfield, 2002). Despite this, insects display a variety of communication behaviors unparalleled in any other class of the animal kingdom (Hölldobler, 1984), matching their vast diversity (see Fig. 1 for a schematic example).

All insect communication can be subdivided into three basic categories: olfactory, acoustic, and visual (Greenfield, 2002). So far, electrical communication, as has been shown in fishes and some amphibians, could not be documented in either terrestrial or aquatic insects (Kramer, 1996). Furthermore, although other forms of energy can apparently be perceived by some insects, e.g., infrared radiation (Schmitz *et al.*, 1997; Schmitz and Bleckmann, 1998) and geomagnetism (Wiltschko and Wiltschko, 1995), no evidence has yet demonstrated that these modalities are used for communication (Greenfield, 2002). The relative importance of acoustic, visual, and olfactory signaling channels can vary widely in different insect taxa, with no particular species excelling in all three communication modalities (Lewis, 1984). However, olfactory communication appears to be the predominant signaling mode prevailing in most studied insect taxa so far (Greenfield, 2002). It is hypothesized that this dependence on and high preference for

Fig. 1 Schematic overview of intra- and interspecific communication and information transfer in a hypothetical insect. Depicted is intraspecific communication between the sexes (i.e., mate finding and female choice) and within the sexes (most commonly occurring as aggregation or male competition) as well as interspecific communication as eavesdropping behavior (e.g., predators using sex pheromones as kairomones), host finding (e.g., parasitoids of eggs from other insect species), or food localization (e.g., phytophagous insects). All of these examples are further described in the main text with concrete examples in all three main insect communication modalities, acoustic, visual, and olfactory.

olfactory communication has evolved over the long period of adaptation to a terrestrial and partially airborne life style after the switch of ancestral insects from primarily marine environments (Missbach *et al.*, 2014).

Acoustic Communication

Among all terrestrial animals, only insects and vertebrates have evolved the capability to produce, detect, and behaviorally respond to 'sound', generally defined as wave motions originating from a source of vibration and transmitted through a medium, irrespective of that medium being air, water, or a solid substrate (Claridge, 2005). It has been proposed that sound production in insects can be subdivided into five categories (Ewing, 1989; Claridge, 2005):

Vibration ('Tremulation')

This category includes vibrations of insect body parts relatively unspecialized for sound production, e.g., the abdomen or wings. Wing vibration has evolved as a means for species-specific communication and mate recognition in many insect species, e.g., swarming mosquitos (Roth, 1948), *Drosophila* fruit flies (Bennet-Clark, 1971) and *Nasonia* jewel wasps (Diao, Ritchie, van de Zande, and Beukeboom, unpublished data). 'Tremulation' has been suggested as a more specific term for this type of sound production to differentiate it from the more general term 'vibration' (Claridge, 2005).

Percussion

Active percussion on either substrates or other body parts is distinct from the sound emissions resulting from tremulation that mostly originate as by-products. For instance, in Australian whistling moths (Bailey, 1978) and some cicadas (Boulard, 2005), percussion of one body part against another has apparently evolved into specific communication systems. In termites (Howse, 1964) and stoneflies (Stewart and Sandberg, 2005), sound signaling by percussion of the substrate with the tip of their abdomina is a well-known mechanism, whereas males of a certain bushcricket species (*Meconema*) actively stamp the substrate with one of their hind legs to produce patterned sound signals (Ragge, 1965).

Stridulation

The wide-spread and well-studied mechanism of stridulation constitutes the creation of friction by rubbing specialized body parts against each other in a regular pattern (Ewing, 1989; Claridge, 2005). Stridulation has been found in at least seven different insect orders, including Orthoptera (grasshoppers, locusts, and crickets), Hemiptera (true bugs), and Coleoptera (beetles), and in most of them, it apparently evolved several times independently, mostly in the context of sexual signaling and mate attraction (Claridge, 2005; Matthews and Matthews, 2010).

Click Mechanisms

The deformation of specialized membranous areas of the cuticle, i.e., a tymbal, is most commonly achieved by contraction and relaxation of special insect body musculature, resulting in a series of 'clicks' allowing for rapid repetitions of characteristic sound patterns (Wessel *et al.*, 2014). The best known example for this particular sound production are the loud mate attraction sounds of cicadas (Matthews and Matthews, 2010; Wessel *et al.*, 2014), but it has also been described in other insect groups such as certain Lepidopteran families (Sales and Pye, 1974).

Air Expulsion

An unusual and rare insect sound production mechanism, the function of these exhalatory sounds, most often expelled via the tracheal spiracles, is generally not well-understood. One of the best-known examples is the European hawkmoth or Death's Head Hawk, *Acherontia atropos*, which forcibly expels air through its mouthparts for a loud, distinctive sound (Busnel and Dumortier, 1959). Another example is the Madagascar hissing cockroach, *Gromphadorhina portentosa*, capable of producing loud hisses from a pair of modified spiracles. Adult males have been found to mostly hiss during courtship, copulation, and aggressive encounters, but also when disturbed (Nelson and Fraser, 1980).

The loudest insect sound detected so far has been measured in a certain African cicada species, *Brevisana brevis*, where it reaches up to 106 decibels and can maintain this level up to 50 cm from the source (Matthews and Matthews, 2010). In comparison, male Asian corn borer moths (*Ostrinia furnicalis*) use very low intensity courtship songs of only 46 decibels with a range of just 1 cm, produced by male-specific scales on their forewings and the mesothorax (Nakano *et al.*, 2008). Apparently, this very restrained acoustic communication behavior has evolved to form a private, close-vicinity communication channel between male and female moths as protection from interference of male competitors and potentially eavesdropping predators (Conner, 2014).

For sound detection in insects, in general, specialized stretch receptor organs need to be present called tympanal organs, fitted with an exterior membrane (tympanum) and an air cavity behind it for detecting the pressure of sound waves transmitted through air or water (Hoy and Robert, 1996). Since the tympanum needs to exceed a certain minimum diameter in order to be fully functional, i.e., uphold the extreme tension to respond to sound effectively, insect body size is generally considered a constraining factor (Fletcher, 1992; Rodríguez *et al.*, 2005). Indeed, smaller insects generally lack tympanal organs and thus the ability to actually hear sound over long distances traveling through air or water (Bennet-Clark, 1998; Roces and Tautz, 2001). However, if sound is

considered in its broader definition as wave motions originating from vibrations that can be transmitted through any kind of medium, most insects actually can detect short-distance vibrational signals through different kinds of solid substrates (Hoy and Yack, 2009). This has also been described as 'seismic communication', and it has been hypothesized that this apparently wide-spread but understudied form of insect communication has evolved from the capability to detect self-induced body movements through so-called 'proprioceptors'. This potentially explains the body-wide distributions of these receptor organs in most studied insect taxa so far, as opposed to the evolutionary and developmentally constrained cranial position of almost all known vertebrate ears (Hoy and Yack, 2009).

Visual Communication

Although insects tend to rely more heavily on their other sensory modalities, visual communication still plays a major role in certain insect taxa (Matthews and Matthews, 2010). Perhaps most prominently, in the orders Odonata and Lepidoptera, particularly sophisticated color vision has evolved. Whereas Lepidoptera also rely on olfactory communication, Odonata apparently have exploited visual communication as their primary signaling modality, possessing greatly reduced antennae whose removal does not seem to impair their capability of prey capture and navigation (Matthews and Matthews, 2010).

The compound eyes of insects are composed of single units called ommatidia which, in turn, are composed of a facet lens, a crystalline cone, surrounding visual pigment cells as well as a set of photoreceptors (Nilsson, 1989). The visual pigments of the photoreceptors determine the spectral sensitivity, whereas actual photodetection primarily takes place in the rhabdomeres, a cylindrical structure in the photoreceptors, where the absorbed light is transduced into a neural signal. Insect vision is generally based on three major photoreceptor classes, specialized on different wave lengths of the light spectrum (Smith and Goldsmith, 1990): near ultraviolet (300–400 nm), cyan/blue/violet (400–500 nm), and orange/yellow/green (500–600 nm). Insect compound eyes directly connect to the optical lobe, the visual center of the insect brain, processing the perceived light signals to detect motion, colors, or other patterns of interest (Stavenga, 2002).

Insect color vision has been particularly well-investigated in butterflies and the honey bee, with the three photoreceptor classes playing major roles for their exceptional capacity to detect and discriminate between very distinct color sets (Stavenga, 2002; Briscoe, 2008). Whereas both honey bees and butterflies rely heavily on color vision in food foraging, particularly concerning the distinction of a vast array of flower coloration patterns (Menzel and Backhaus, 1989; Stavenga, 2002; Kelber *et al.*, 2003), butterflies have also extensively exploited color preference and distinction in mate choice and intraspecific male-male interactions (Lederhouse and Scriber, 1996; Frentiu and Briscoe, 2008, see also Fig. 1). This is particularly evident in emerging patterns of apparent co-evolution between butterfly color perception capabilities and their vast and distinguished wing coloration patterns (Briscoe, 2008; Koshitaka *et al.*, 2008).

Another particularly well-investigated form of visual communication in insects occurs in the Coleopteran family Lampyridae (fireflies), where many nocturnally active species emit precisely timed photic signals consisting of distinctive and clearly visible bioluminescent flashes or glows to attract mates (Lloyd, 1969; Ohba, 2004; Lewis and Cratsley, 2008). Interestingly, in diurnal Lampyridae species, olfactory communication appears to be the more prominent signaling modality (Lloyd, 1972; De Cock and Matthysen, 2005).

Olfactory Communication

In contrast to visual and auditory signaling, whose emission and reception are largely governed by quantitative differences, chemical signals display a more discrete character (Symonds and Elgar, 2008). The ability to perceive specific chemical compounds is mostly dependent on the presence or absence of the respective receptor molecules, leading to a tight linkage of sender and receiver (Bargmann, 2006).
